After 1830 the use of conversational therapy was discussed more fully. In that year, Conolly(31) stated that the "great business" of the doctor was to instruct, amuse, soothe, converse with, and advise his patients. In 1833 Allen wrote a little more extensively than most doctors on this subject. He praised "intellectual therapy" and mentioned some of his own methods. He saw his goal largely as one of making "truth visible" to the insane, a purpose previously mentioned by Chiarugi and Reil. Allen maintained that with intelligence and insight the doctor could trace his patient's peculiarities to their origin. He gives an example of his treatment of a depressed patient: summoning the man to him each evening, Dr. Allen related his own life history in detail, keeping the patient's attention by leaving off each time, like Scheherazade, at a point of great interest, and at the same time guiding the patient by subtly introducing his views about the patient's bad habits and the best way to overcome them.

The rise of phrenological thought in the 19th century introduced another concept into psychotherapy. In 1831 Combe emphasized that one should first know human nature in general and then use phrenology to understand the individual patient's personality; thereby a type of analysis came into being. The phrenologist-physician tried to help the patient understand that he had become ill because some of his motivations and faculties (associated in theory with specific areas of the brain) were over- or under-developed. With the aid of his physician the patient was to repress the over-active faculties and at the same time strengthen the weaker ones, so that his personality would come back into balance and he would recover his health(32).

If an interest in the patient's fundamental personality was a relatively later development, so was any real insight into the relevance of the doctor's personality, although there were a number of statements about how the doctor should behave towards his patients. In brief, he should be intelligent, courageous, firm but kind, understanding, hopeful, tender, cheerful, and upright. Per-

haps the first recognition of variations in a doctor's personality is Haslam's admission that he lacked the lightning in his eye, the thunder in his voice, and the majestic bearing that some considered requisite for the ideal psychiatrist.

Physicians recognized that therapeutic acumen was something of an art. Haslam said that only by trial and error could the doctor hope to acquire what we today would call an effective psychotherapeutic approach, and that this could not be taught and therefore would perish with the individual doctor. Because of this difficulty in communication, it is likely that each doctor developed more techniques for dealing with his patients than appear in the literature. Both Cox and Haslam stressed that before he could hope to gain the confidence and respect of the patient the doctor must learn to control himself and not become agitated or upset. Trotter pointed out that this control was difficult for a young doctor to learn, and that he needed knowledge about human nature and extensive study of living man before he could develop this art. Burrows stated that tact was the pivotal factor in the doctor-patient relationship, and that it was an intuitive art that could not be taught, although it might be elicited by chance and then developed by experience. He also stressed the need for delicacy and the value of intelligence in approaching the patient.

Allen seems to be the only doctor of this period to recognize and write about the doctor's personal response to his patients. He recorded a case of a woman who so exhausted him emotionally that he himself became depressed and was forced to transfer her to the care of his wife. This woman also overwhelmed his wife at times, so that Mrs. Allen was forced to threaten her with separation and transfer unless the patient stopped complaining.

DISCUSSION

The various therapeutic approaches discussed here arose from associational or sensational psychology, from the older faculty psychology and its newer modifications by the Scottish philosophers, and from humanitarianism, romanticism, and phrenology, to name only some of the more obvious

sources. From the depths of each doctor's individual personality came methods peculiarly applicable to one or more types of emotional disturbance.

Although we have not attempted to study the literature on the milder psychiatric diseases, we have found evidence that certain doctor-patient concepts were employed in this area before being applied in what we today would term psychoses. Since some of the techniques can be traced to the Greeks, one may ask what is novel, by 1840, in the doctor-patient relationship. The answer seems to lie in the trend towards increasingly complex but more explicit psychotherapeutic methods which are meaningful to the psychotherapy we practice today.

LATE RESULTS OF ORBITAL UNDERCUTTING

Report of 76 Patients Undergoing Quantitative Selective Lobotomies¹

WILLIAM BEECHER SCOVILLE, M.D.²

Since 1948, when the writer first proposed cortical undercutting(1) as a method of interrupting cortical connections from various surface areas of the frontal and temporal lobes, he has performed the selective leukotomy operation of "orbital undercutting" of the frontal lobes on 94 private patients and 41 state institutional patients in Connecticut. They constitute two distinct categories of patients both in the malignancy of their mental illness and in their cultural backgrounds. Previous reports have been made on the early results in various diagnostic categories, ranging from benign psychoneuroses to malignant schizophrenic psychoses(2, 3, 4, 5). Observations have been published on certain physiologic changes resulting from stimulation and destruction of anatomic areas within the frontal and temporal lobes(6, 7). Presentation is now made of the late results of orbital undercutting, an operation which has largely replaced other selective operations in the author's hands.

HISTORICAL

Trends and cycles in psychiatric treatment, as in clothes, change inexplicably. In the latter half of this century, the organic Kraepelin school has successively been followed by psychoanalysis, shock therapy, lobotomy, and, more recently, by newer drugs and chemotherapies. The results in each have been encouraging but the public's acceptance has waxed and waned in a manner quite lacking in objectivity. Probably the greatest benefit of the surgical, electrical and chemical therapies has been a luring of psychiatrists back to the organic medical fold from those Freudian fields of mystic environmentalists. Although at present in both America and Britain, psychosurgery is in temporary eclipse to ever newer trends in drug therapies and certain

shock therapies, the writer believes that psychosurgery continues to have a very definite place in the treatment of mental disease.

Drug therapy has definite limitations in the more intractable emotional and psychotic disturbances. Shock treatment is largely limited to use in depressive diseases; it fails to prevent recurrences in these depressions; it may increase anxiety, tension and somatic symptoms in the chronic neuroses; and it is unsafe in the elderly age group. Emphasis is made on the permanent sequelae of insidious mental blunting and measurable memory loss resulting from repeated courses of shock treatment, exactly similar to those changes seen in the recurrent brain injuries of prize fighters and other accident prone individuals. All too frequently these late effects are blamed on the natural course of the patient's disease.

Complete lobotomy has been largely replaced by limited selective operations, especially in the benign psychoneuroses and depressions and in those schizophrenic patients possessing higher cultural backgrounds(8-14). The classical standard lobotomy or leukotomy is now advocated only in deteriorated schizophrenic patients of low cultural level requiring continuous restraint and nursing care. Even in such cases selective undercutting of the superior convexity of the frontal lobes gives a comparable benefit with less personality blunting(1). However, the principal application of selective lobotomies is in the neuroses, depressions and certain senile states. Such selective lobotomies, especially orbital undercutting, are now advised by the author as the treatment of choice in those recurrent depressions requiring more than a limited course of shock treatment; in seriously disabling anxiety-tension states; in intractable obsessive-compulsive syndromes without excessive narcissism and egocentricity; and in certain anxious, agi-

¹ Presented before the Royal Society of Medicine, London, England, Feb. 9, 1960.

² 85 Jefferson St., Suite 401, Hartford 14, Conn.

tated elderly people; this latter group giving unexpectedly gratifying results.

OTHER OPERATIONS

The chief criterion for the type and location of the newer selective operations should be a maximum of improvement with a minimum of personality deficit, using a technique which can be exactly duplicated from patient to patient. Bilateral medial quadrantic sectioning or electrocoagulation (14, 8) satisfies the first criterion very well, but precise duplication is difficult because of a blind sectioning of internal white matter containing concentrated bundles of fibres, using electric or chemical agents without measurable control over the spread of destruction. The transorbital lobotomy of Fiamberti (15) and later Freeman (16), in spite of its extreme simplicity, is undesirable in the more benign illnesses because of its complete lack of precision. When done, it should be performed by surgeons and not psychiatrists. Bilateral fractional ablations of the medial temporal lobe (5) have not shown sufficient benefit to warrant their use in mental illness and may cause memory loss (17). Certain psychosurgeons have stressed the role of the rostral cingulate area and its effect on obsessive-compulsive thinking. Cairns (18) and more recently Lewin (19), LeBeau (9), Livingston (20) and Ward (21) have done modified undercutting or resections of this area. The writer, in more extensive interruptions of the rostral cingulate cortex, failed to note an appreciable specificity (1). In the more malignant psychoses occurring in well preserved personalities, the writer has advocated undercutting of the superior convexity (1), an operation duplicated in later years by McKissock (10) with his rostral leukotomy and Pool (22) with his bimedial prefrontal lobotomy.

However, to an increasing degree, the writer has limited his psychosurgery to the operation of orbital undercutting because of its simplicity; the absence of personality blunting; the preservation of adjacent and deep blood supply, and most particularly because of the ability to duplicate in successive patients, under direct vision, a quantitative sectioning of connections from measured surface areas. It is gratifying to

know that distinguished surgeons of the British school, especially Northfield (23), Lewin (12), and Knight (24), and of the Scandinavian school, Busch (2) and Sjoqvist (2), have reached similar conclusions in their advocacy of this procedure, called in England orbital leukotomy, in Sweden orbital undercutting, and in Denmark orbito-medial leukotomy.

CASE SELECTION

The writer, in preparing for this address before the Royal Society of Medicine some 10 years after his initial presentation on "Cortical Undercutting" has elected to review the late results of those cases limited to orbital undercutting and omitting mental defectives. Out of 92 private patients, 42 have been followed for more than 4 years (an arbitrary minimum in order to permit studies on approximately 50 patients), a maximum of 11 years and an average of 6.2 years. Of this "late follow-up" series, 12 had malignant schizophrenic types of psychoses, 30 had benign; and from this latter group all patients over 65 years of age were additionally studied in a separate category. Specifically, they fall within the categories of schizophrenia (5 cases), pseudoneurotic schizophrenia (7 cases), depressions (14 cases), neuroses (16 cases), and "elderly" (14 cases). The majority of these patients were operated upon on the private neurosurgical service of the Hartford Hospital and discharged to their homes. They represent patients of some private means from appreciably high cultural backgrounds. The writer has elected to separate this group from that of 34 cases of schizophrenic patients followed over a 10-year period in 2 state mental institutions. It was expected that the late results would be poor in this latter category, as they were derived from patients of poor economic and cultural background, often seriously deteriorated, and without facilities for care or rehabilitation outside of institutions. Follow-up reports have been obtained from members of the immediate family or supervising physician following direct telephone communication, printed questionnaires, and personal examination in the majority of private patients. Much difficulty was encountered because of a scattering of such

patients following operations to the far corners of the United States.

In age and sex groups, the institutional and private categories were roughly comparable, the schizophrenic and pseudoneurotic schizophrenic patients being relatively young with an average of 34 years and three-fifths undergoing operation under the age of 40. The psychoneurotic patients were in the middle age group with an average of 54 years and two-thirds above the age of 40. The depressed patients were older, averaging 64 years, all of them being operated upon over the age of 40, and the "elderly" group averaged 72 years, no case being younger than 65, the majority in their 70's and three in their 80's. Complications and physiologic observations were recorded on a total series of 128 cases undergoing orbital undercutting.

RESULTS

Psychiatric—(See Tables 1 and 2). The results are tabulated under the headings of 1. "Marked benefit," constituting a clinical cure or marked improvement, permitting the patient to live at home and return to his former occupation; and 2. "Significant benefit," constituting moderate improvement, marked improvement or clinical cure, as described by relatives and supervising doctors (described in more detail in an earlier publication⁽²⁾). Two other headings have been added in Table 1 to indicate a progression or regression in improvement over the years of study. "Early" follow-up studies were made between the 3rd and 12th months postoperatively.

The "late" results (Table 1) in the private group of patients revealed a satisfactory and significant improvement in all diagnostic categories with certain unexpected variations. The best late results occurred, to our surprise, in the schizophrenic group. All 5, or 100%, showed a marked benefit as compared to 20% with early benefit. This was confirmed to a less dramatic degree in the state hospital cases. The depressions and "elderly" states closely approximated this excellent result, showing 93% and 86% respectively having marked improvement as compared to 64% and 50% in the early results. The psychoneuroses and pseudoneurotic schizophrenic groups

had an appreciably lower percentage of marked improvement, being 63% and 57%, respectively, but again increased considerably over the early results. In fact, the pseudoneurotic schizophrenics showed the same degree of dramatic increase in late benefits as did the schizophrenic categories. If one is less demanding in one's evaluation, using moderate or "significant" benefit rather than a marked benefit in classification, all 5 categories are in reasonable approximation to each other, ranging from 71% to 93%. Here again the psychoneuroses proved more intractable than schizophrenics.

Although the number studied in each category of private patients is admittedly too low for great statistical significance, the *continuing* improvement of all patients over our 4 to 11 year studies and the especial and unexpected late benefits in all 46 schizophrenic patients is deemed statistically significant. The writer anticipated regression in some one-half of all cases, especially in the schizophrenic patients. This proved not to be the case, total late "marked" benefits being nearly double that of the early (76% as opposed to 40%). The schizophrenic patients lead in late improvement, increasing from 20% to 100%. The depressions and all "elderly" states were a close second, and it is gratifying to observe the absence of a single appreciable relapse in the depressive patients over a 4 to 10 year follow-up. Obsessive-compulsive psychoneuroses and schizophrenic patients with predominantly neurotic overlays proved the most intractable. In studying the diagnostic categories in relation to an advance or a regression from the original improvement, all showed a preponderance of the patients advancing. Relapses to a significant degree occurred only in the obsessive-compulsive symptomatology.

In studying the 34 cases of schizophrenic patients of the lower economic and cultural scale committed to two state institutions, a similar unexpected late improvement occurred. In fact, in one of the two institutions the late results showed 6 times as many patients exhibiting marked improvement. Orbital undercutting, when performed on schizophrenic patients within state hospitals, resulted in "significant" late benefit

TABLE 1
PRIVATE PATIENTS
RESULTS

Diagnostic Category	No. of late follow-ups (average—6.2 years)	Average age (in years)	MARKED BENEFIT OR CLINICAL CURE		"SIGNIFICANT" BENEFIT **		Advance from original improvement	Regression from original improvement
			Early	Late	Early	Late		
Schizophrenia (9 patients)	5	34	1 (20%)	5 (100%)	3 (60%)	5 (100%)	5 (100%)	0 (0%)
Pseudoneurotic schizophrenia (11 patients)	7	34	1 (14%)	4 (57%)	4 (57%)	5 (71%)	4 (57%)	1 (14%)
Psychoneuroses (37 patients)	16	54	6 (38%)	10 (83%)	16 (100%)	12 (75%)	8 (50%)	6 (38%)
Depressions (35 patients)	14	64	9 (64%)	13 (93%)	13 (93%)	13 (93%)	6 (43%)	1 (7%)
Total patients 92	42	47	17 (40%)	32 (76%)	36 (86%)	35 (83%)	23 (55%)	8 (19%)
Elderly* (29 patients)	14	72	7 (50%)	12 (86%)	13 (93%)	12 (86%)	7 (50%)	2 (14%)

*Note: Omitted from the total inasmuch as they are duplicated under Psychoneuroses and Depressions.

**Note: "Significant" benefit represents all patients showing moderate or marked benefit or clinical cure.

STATE HOSPITAL CASES, 10 YEAR FOLLOW-UP ON
SCHIZOPHRENIC PATIENTS

	Cases	Average Age	Marked Improvement		"Significant" Improvement (moderate and marked)	
			Early	Late	Early	Late
Conn. State Hospital	18	34	6 (33%)	11 (61%)	13 (72%)	15 (83%)
Norwich State Hospital	16	43	1 (6%)	6 (38%)	6 (38%)	11 (69%)
Total	34	39	7 (21%)	17 (50%)	19 (56%)	26 (76%)

in 76% and "marked" late benefit in 50% of patients. This compares very favorably with the results of other more radical lobotomy operations.

In summation, in the study of 42 private patients followed from 4 to 11 years, with a separate study of 14 "elderly" patients found in the depressed and psychoneurotic groups, the late results were superior in the categories of schizophrenia, depression and the "elderly," averaging 100%, 93% and 86%, respectively; while the psychoneuroses and pseudoneurotic schizophrenics showed 63% and 57%, respectively; or an overall average of 76% with "marked" benefit and 86% with "significant" benefit. Although showing much less overall benefit, patients in the lower economic and cultural range showed an equal amount of late over early improvement.

A warning should be given as to the necessity of using a very conservative degree of undercutting in the older age groups, in order to prevent personality deterioration(3, 7). When conservatively performed, these elderly patients appeared in better contact with their environment, with a restoration of sleep rhythm, cheerfulness and social outgoingness not previously present; indicating that their pre-operative psychopathology was not due to simple aging. It should also be pointed out that psychoneurotic patients suffering from anxiety, tension and real emotional suffering do much better, both early and late, than those with rigid personalities exhibiting much narcissism, egocentricity, and masochistic enjoyment of their ritual pat-

terns. In these latter patients, orbital undercutting brings out their underlying selfishness to a distressing degree.

PHYSIOLOGIC RESULTS AND COMPLICATIONS

A review of the late results of orbital undercutting showed little changes from those described in earlier papers(1). Actually, all complications occurred in the early stages. In recapitulating them, it should be stressed that the majority occurred in elderly persons. There were two deaths in 93 persons, one from cardiac failure on the first postop day in a patient 76 and one on the second postop day following a convulsion in a patient of 66 years of age. One 83-year-old patient showed a marked one-day improvement followed by a sudden confusional and stuporous state thought to be due to thrombosis. Two elderly patients fell out of bed, one suffering a fractured hip and the other an intracerebral clot requiring secondary evacuation and lobectomy with deterioration thereafter. These unfortunate occurrences have resulted in our placing all elderly post-operative lobotomy patients in a net cage (25) fastened over the bed for the first 24 to 48 hours, unless special nursing care is available.

When pseudoneurotic schizophrenic patients undergo selective lobotomies, relatives and physicians must be warned in advance of the possibility of bringing to the surface underlying schizophrenic symptoms. Such patients apparently cloak their psychotic delusions in an obsessive-compulsive or somatic conversion overlay. Provided

there is advance warning, lobotomy appears justified, inasmuch as it enables the patient to ventilate his underlying delusions and make better contact with society. In only one case was a later commitment found necessary, and that only after a 10-years' interlude.

There were no infections. There were three blood clots requiring open drainage, one following a fall from bed. Urinary incontinence and temporary confusional state has been largely absent, in comparison with certain other lobotomy patients.

Convulsions: In attempting a 10-year follow-up in the state hospital cases, great difficulty was encountered in obtaining an honest tabulation of isolated convulsions, largely because of neglect of anti-convulsant medication in deteriorated patients and proper recording by ever changing personnel. However, in this series, 29% of 42 had one or more eventual seizures. In a series of 121 private patients, of which 52 were followed an average of 6.2 years, there have been 7 (5.7%) known patients who developed isolated seizures more than one week postoperatively. Only one of these patients had more than one seizure, indicating easy controllability by dilantin; and only one patient had seizures more than 4 years postoperatively, the others occurring in the first, second or third postoperative years. An additional 6 patients had seizures within the first day after operation without later recurrences, attributed to a too radical extension of the undercutting upwards and posteriorly into the septal area, a known epileptogenic area(7).

The physiologic effects of orbital undercutting have been described in previous papers. Of both scientific and therapeutic importance has been the observation that the uncus area as well as the septal area is sharply epileptogenic. Damage to the septal area may affect adversely states of consciousness and/or confusional states, such occurring in 5 out of 121 patients undergoing orbital undercutting(7). Hence, caution is urged against too radical posterior or superior extension of the orbital undercutting, especially in elderly persons. The line of cleavage must lie exactly at the junction of grey and white matter as one approaches the optic chiasm.

DISCUSSION AND CONCLUSIONS

In reviewing late with early results of orbital undercutting, the writer is of the impression that selective lobotomies, especially when utilizing the precise method of cortical undercutting, continue as procedures of great merit in the treatment of both benign and malignant mental disease. The newer drugs and electric shock cannot yet replace them in the treatment of the more intractable neuroses, recurrent depressions, senile agitated states and certain schizophrenic patients of high cultural background. They offer the advantage of greater intensity than drug therapy, and of fewer relapses than offered by shock therapy. As demonstrated in earlier studies, the results in depressions have been little short of dramatic; the results in certain intractable obsessive-compulsive neuroses and in anxiety-tension states, especially in the aged are more than satisfactory; and similarly drug addiction and alcoholism when due to panic, anxiety or social discomfort are markedly benefited. Caution must be given against using this operation for persons having constitutional psychopathic personalities especially those showing criminal or alcoholic tendencies, as well as for persons showing those obsessive-compulsive traits overlying extremely narcissistic and egocentric personalities. Epileptic seizures appear to occur in the early postoperative years and can be easily controlled by dilantin therapy when occurring in cooperative persons not already deteriorated.

Unexpected results of a progressive and ultimately superior benefit followed orbital undercutting in schizophrenic patients derived from high cultural backgrounds. Neither depressive nor elderly patients have shown appreciable relapses in long-term studies. The psychoneurotic patients of the obsessive-compulsive type have proved more intractable, with more variability and more relapses. The category of pseudoneurotic schizophrenia in younger age groups is not uncommon, and underlying malignant schizoid symptoms are obscured by a superficial constellation of both obsessive and compulsive symptomatology. The neurotic overlay can be removed by

orbital undercutting bringing to the surface deeper psychopathology.

In a study of the psychopathology following section, stimulation or resection of various areas of the frontal and medial temporal lobes, the writer must conclude that interruption of surface areas only indirectly affect the fundamental mechanisms of mental disease and, with the exception of depressions, the benefit by selective leukotomy lies more in a blunting of higher sensitivities than in a changing of disease patterns. In the future, it is hoped that stereotaxic, ultrasonic or chemical approaches may be found to the deeper midline, diencephalic, limbic and reticular systems. Unfortunately, to date lesions made in such areas produce rather than alleviate psychotic delusional and affective aberrations.

SUMMARY

1. Psychosurgery continues to have definite applications, especially in the involutional and cyclic depressions, the agitated states of the elderly, the better preserved schizophrenics, and the intractable psychoneuroses, especially when suffering from anxiety or tension.

2. It is preferred to shock treatment in those depressions requiring more than short courses of shock treatment because of less emotional blunting, memory loss and relapses.

3. Agitated depressed senile states react more favorably to limited lobotomy operations than those in the younger age group.

4. Complete lobotomy has been replaced by limited selective operations. Undercutting of the orbital cortex offers the advantage of a precise technique under direct vision in an area causing appreciable lift in mood, lessening of anxiety and a minimum personality blunting.

5. The late results in orbital undercutting when studied in the separate categories of depressions, agitated senile states, schizophrenia, pseudoneurotic schizophrenia and intractable psychoneurosis have in most cases continued to show an improvement rather than regression or relapse. It has done so to a far greater degree than was anticipated, especially in schizophrenic patients of high cultural background.

6. Complications, including seizure for-

mation, occur in the early rather than the late follow-up studies.

COMPARATIVE CLINICAL EXPERIENCE WITH FIVE ANTIDEPRESSANTS

JOHN P. HOLT, M.D., ELEANORE R. WRIGHT, M.D.,
AND ARTHUR O. HECKER, M.D.¹

Clinical and non-clinical reports, too numerous to list, have appeared describing the actions and uses of the newer antidepressants. In general, these reports agree that the drugs are effective; many also indicate that they are superior to the amphetamines and tranquilizers in specific types of depression. In view of these reports, we decided to undertake a study of 5 of these new drugs to compare their effectiveness in hospitalized, depressed patients. The drugs chosen were: isocarboxazid (Marplan); nialamide (Niamid); phenelzine (Nardil); pheniprazine (Catron), (all monoamine oxidase (MAO) inhibitors); and imipramine (Tofranil)-(a non-monoamine oxidase inhibitor).²

Since it is generally recognized that precise diagnostic classification of depressed patients is difficult, we decided to select patients in accordance with Lehmann's(1) definition of the depressive syndrome which is based on the following triad of primary symptoms: a sad, despairing mood; a decrease in mental productivity; and a reduction of drive and retardation (or agitation) of expressive motor responses. In addition to these primary symptoms, attention was also given to various secondary symptoms (see Table 1). Moreover, because some investigators(2, 3) believe that clinical response to antidepressant therapy occurs through the control of symptoms resulting from induced biochemical alterations rather than from true reversibility of the basic cause of the depressive disorder, we decided to use the patients' pre- and post-treatment symptoms as a direct measure of the drugs' activity.

In all, 134 patients were selected, but only 100 (20 patients on each of the 5 drugs) completed the evaluation; 28 were dropped because they received concomitant treatment with either a tranquilizer or

ECT; 4 because they refused to take medication; and 2 died from organic causes unrelated to drug therapy. Diagnostically, the patients represented a relatively heterogeneous group (Table 2), but all possessed sufficient primary and secondary symptoms to indicate a well-established depressive syndrome. Of these patients, 62 were women and 38 were men; 80% of them were between the ages of 25 and 35 (range of ages: 18 to 72 years).

METHOD AND MATERIAL

Prior to receiving any of the drugs, all the patients underwent a complete physical examination; laboratory tests, including a CBC, urinalysis, alkaline phosphatase,

cephalin flocculation, serum bilirubin, and urine urobilinogen, were done on all patients. In addition, each patient was interviewed to determine his current mental status, and to allow completion of the symptomatic check list (Table 1). Patients were assigned to one of the drugs in rotation until equal numbers of patients from each of the

broad diagnostic categories had been placed on each of the drugs.

All medications were administered orally in accordance with the dosage schedules shown in Table 3. Initial doses were given for two weeks and, if no significant symptomatic improvement was noted, were gradually increased by unit-dose increments at intervals varying from 2 to 6 days until the maximum dose was reached. Maximum doses were given for 2 to 4 weeks, at which time the dose was decreased to a level (maintenance dose) which produced continuous symptomatic improvement. When the maintenance dose was given for 3 or 4 weeks without producing additional improvement, the dose was reduced to a level (minimum dose) which kept the patient from relapsing. The minimum dose was then continued for at least 2 weeks, after which time the patient was evaluated to determine the degree of improvement that had occurred. Blood pressure measurements were made daily during the first week of drug therapy, and twice weekly thereafter. Each patient's response to treatment was recorded: 1. Daily, in the progress notes of the ward physicians; 2. Weekly, in interviews with the senior investigator, and in the reports of the nursing staff; 3. Periodically, in reports of the occupational and industrial therapists.

After 16 weeks of treatment, each patient's clinical progress was determined by reviewing the various aforementioned reports. A final interview was conducted to complete a second check list of the

depressive and somatic symptoms still present. Patients who were discharged from the hospital prior to the 16th week of treatment received a final evaluation several days before being discharged. Results of treatment were judged as follows :

Maximum Improvement—remission of all symptoms. Patients in this category were either discharged or were considered eligible for discharge.

Marked Improvement—remission of all primary depressive symptoms and considerable relief of secondary symptoms.

Moderate Improvement—partial remission of all or complete remission of at least one-half of the presenting symptoms.

Minimal Improvement—little or no change in the primary depressive symptoms, but a slight to considerable remission of at least one-half of the secondary symptoms.

No Improvement—no change in symptoms, or severe aggravation of the basic psychoses.

Significant levels of improvement included the ratings of maximum, marked, and moderate improvement.

CLINICAL, SYMPTOMATIC AND LABORATORY RESULTS

The patients' clinical response to the various antidepressants, as derived from the daily, weekly and interval reports of the various staffs at the hospital, is shown in Table 4. Because of the small number of patients in each rating category, the results have been "pooled" and are shown as the

number obtaining "Significant Improvement." An inspection of the number of patients in each of the 5 improvement categories indicates that phenelzine produced the largest number of maximum and marked improvements (5 and 7, respectively), while nialamide produced the fewest (1 and 3, respectively); the response to the other drugs was between these extremes. The largest number of failures were observed in patients receiving pheniprazine (5) and nialamide (4).

Results based on the patients' symptomatic improvement are shown in Table 5. With one exception, a review of the effect on individual psychic and somatic symptoms failed to show any really significant differences between the drugs. The exception indicated that imipramine and phenelzine, particularly the latter, afford greater relief of anxiety and agitation than the other drugs. From an overall point of view, phenelzine and imipramine had the greatest effect on relieving psychic symptoms (78.6% and 75.6%, respectively) and somatic symptoms (78.8% and 81.2%, respectively).

Despite the similarity of depressive symptomatology of all the patients, it would appear that individual improvement depended, to some extent, on whether the patient had a primary depressive reaction or depressive symptomatology associated with another psychotic reaction. For example, of the 50 patients of the former type, 39 (78%) obtained significant improvement; 18 (36%) of them were discharged or eligible for discharge. Of the 30 patients with

underlying schizophrenic reactions, 14 (47%) obtained significant improvement; none was discharged or became eligible for discharge. Of the 20 patients with underlying organic brain disorders, 8 (40%) obtained significant improvement. All 5 of the patients whose disorder was associated with alcohol intoxication obtained this level of improvement; one of these patients was discharged.

Within the 3 diagnostic groups, response to treatment was quite similar, regardless of the drug being used. In the group with primary depressive reactions, patients with rather severe retardation and inhibition of expressive motor responses seemed to experience the most definitive remission of symptoms. This was particularly true of patients with involutional psychotic reactions (without severe agitation) and manic-depressive, depressed reactions. Response in patients in whom anxiety and agitation were major symptoms was inconsistent. The response of patients with hyperactive tendencies was often preceded by increased restlessness and other manifestations of the neurosis or psychosis. Patients in the group with primary depressive reactions generally exhibited initial symptomatic improvement at the end of 2 weeks, and optimal improvement between 4 and 6 weeks. As would be expected, there were exceptions to this generalization in both directions. Some of the patients, particularly those with involutional or manic-depressive, depressed reactions, responded sooner than two weeks. Regardless of the diagnosis, patients with histories of recurrent depressive episodes and who had

become increasingly resistant to previous treatment with either ECT or phenothiazines, responded to treatment more slowly, and it was not uncommon for them to remain unimproved until they had been on a drug for 4 to 6 weeks. Initial improvement, however, was of the same character as that noted in the more responsive patients; optimal improvement in these patients usually occurred between the sixth and eighth week of treatment.

The degree of improvement in the group of patients with underlying schizophrenic reactions was not, as previously mentioned, as great as that in the group with primary depressive reactions. Although patients in the schizophrenic group with catatonic reactions seemed to derive the most benefit from treatment, their response was still somewhat unpredictable. For example, all of these patients experienced some improvement, but half of them demonstrated agitation, hostility and mild accentuation of schizophrenic symptomatology as the depressive symptoms were relieved. Patients with paranoid or undifferentiated types of schizophrenia exhibited some improvement in mood, less apathy and somatic symptomatology, usually without accentuation of their underlying disorder. For this entire group, 3 to 6 weeks of treatment were required before any signs of improvement were noted; optimum improvement generally occurred within 6 to 9 weeks. As stated earlier, these patients required maximum doses of the drugs and it was usually on these doses that optimum improvement was noted. If activation or accentuation of the

TABLE 5
SYMPTOMATIC IMPROVEMENT

underlying disorder were to occur, it too occurred on the maximum dose and prompt reduction in dosage was mandatory.

As might be expected, response to treatment was poorest in the group of patients with organic brain disorders. Improvement was limited almost entirely to those who had an acute disorder associated with alcohol intoxication; initial improvement in these patients was seen during the first week of treatment. Initial improvement in the remaining patients with organic disorders was difficult to determine. It seemed to occur somewhere around the third or fourth week of treatment, but never became pronounced enough to affect the patients' general activity. These patients appeared to become a little more active and less hostile, but as this occurred they also tended to become confused, agitated, anorectic and have memory disturbances. In all probability, the concentrated attention the patients received while the study was being conducted contributed to their limited improvement as much as therapy.

Additional efforts to delineate factors

which might have contributed to therapeutic success or failure of the drugs were inconclusive. A slightly higher percentage of women responded than men, but the margin of difference was too small to be meaningful. Age did not appear to be a significant factor. Excluding the elderly patients with concomitant organic brain disorders, older patients seemed to respond as well as younger ones. However, we discovered early in the study that elderly, chronically depressed patients could not tolerate the same doses of the drugs as younger patients. Concurrent chronic physical diseases had little or no effect on any of the drugs' activity, as evidenced by the relatively large number of patients with cardiovascular disease, arthritis, and diabetes who achieved significant levels of improvement.

SIDE EFFECTS

The drugs produced side effects (Table 6), most of which seemed related to changes in the autonomic and peripheral nervous system. As will be noted from the table, phenelzine and pheniprazine pro-

TABLE 6

TOTAL	51	50	26	9	14

duced the fewest side effects of any of the drugs. In most patients, side effects occurred during the first two or three weeks of therapy and were controlled by symptomatic treatment rather than by reducing the dose or discontinuing the drug. Small fluctuations in blood pressure were observed in 34 patients, and persistent lowering of systolic pressure below 100 mm. Hg. was noted in an additional 24 patients. Postural hypotension was observed in 8 other patients. Hypotension occurred more frequently in patients with low initial blood pressures and in elderly patients with pre-existing hypertension. When hypotension occurred late in therapy, it was considered an indication of the drugs' cumulative effect.

The drugs also caused side effects which were indicative of cerebral stimulation. Insomnia was frequently experienced during the early weeks of therapy and was usually controlled by giving a sedative at bedtime. Once the depressive symptoms began to subside, the sleep pattern improved and the sedative could be discontinued. We observed that many patients who had insomnia as a secondary depressive symptom developed motor restlessness that was somewhat similar to that observed with some of the more potent phenothiazines. Fortunately these effects were usually transient and could be controlled by administering a mild sedative or an anti-Parkinsonism agent; reduction in dosage was seldom necessary.

No significant abnormal values were encountered in any of the laboratory studies.

Except for an occasional upper respiratory infection or mild gastrointestinal disturbance, no intercurrent illnesses were encountered which required special adjustment in medication.

CONCLUSION

Based on our results, we feel that all 5 of the antidepressants are effective agents and are generally superior to the amphetamines and phenothiazines in producing remission or relief of primary and secondary symptoms which comprise the depressive syndrome. Generally, the best response to the antidepressants occurs in patients with primary depressive reactions. Most patients with depressive features associated with schizophrenia or organic brain disorders experience significant improvement in depressive symptomatology without experience.

No serious complications or side effects were produced by the drugs. Postural hypotension, excessive psychomotor stimulation and aggravation of schizophrenic symptomatology were the most bothersome side effects and it would appear that each drug has a similar capacity to cause these reactions. Neither hemopoietic nor hepatic toxicity was evidenced during our experience with the drugs.

PROFOUND EXPERIMENTAL SENSORY ISOLATION¹

JAY T. SHURLEY, M.D.²

The nature and range of psychophysiological phenomena evoked in intact humans experimentally exposed in solitude to an environment which profoundly diminishes absolute amounts of sensory inputs has been suggested by Lilly(1). Lilly and Shurley (2) attempted to define relevant physical, physiological, psychological and social conditions for such experiments. Beginning with Bexton, Heron and Scott in Hebb's laboratory(3, 4, 5, 6), many workers(7, 8, 9) have described effects of minimal or partial experimental interference with sensory inputs, or the normal, varied patterning of these, with or without solitude. Bennett (10) and Camberari(11) have used immersion techniques; their findings are more comparable with those reported here. In an attempt to eliminate further some shortcomings of the early experiments, the author redesigned the apparatus and altered critical aspects of the technique. These modifications are briefly reported here, together with an account of some experimental findings.³

METHOD AND PROCEDURE

At the physical level (Figure 1), we aimed at the provision of a constant environment allowing the maximum achievable reduction of ambient physical stimuli, plus the maintenance of a constant level of those inputs impossible to eliminate, such as temperature. A special two room laboratory was constructed at the Oklahoma City Veterans Administration Hospital. The laboratory enabled us to achieve a marked diminution of light, sound, vibration, odor, and taste inputs. A large tank of slowly

flowing water maintained at approximately 93.5 degrees F. (34.5°C.) provided simulated weightlessness, a uniform tactile field, elimination of body wastes, and other advantages for our purpose. Inspired air was kept at a constant low pressure, at 70°F., a relative humidity of 45%, and free of odor and other pollution. Automatic controls and continuous tape recorders completed a virtual self-operating system requiring infrequent attention.

At the physiological level, we aimed at the absolute elimination of all sources of pain and discomfort from body position, pressure ischemia and hollow viscus distention. The subject was positioned so as to remain comfortable, though motionless, for relatively long periods. He was under instruction to inhibit body movements to the maximum degree consistent with comfort. Design of the mask and breathing system (Figure 2) allowed effortless breathing without reduction of oxygen tension and without carbon dioxide pile-up. Neutral buoyancy of the body was carefully achieved by appropriate, low stimulation placements of weights or buoyant, soft plastic material around the mask or body.

At the psycho-social level, we sought subjects with distinct personal attributes. The experimental situation *per se* required a somewhat self-selected volunteer with presumed ability for sensitive and accurate self-observation, and better than average memory, recall, and descriptive powers. In the experiment the subject needed to assume the role of a relatively passive, self-maintaining sensor, recorder, recaller and reproducer, with free time, motivated to communicate his experience fully, freely, and with minimal omission and distortion to the interested, relaxed, minimally active and minimally coercive experimenter (Figure 3). With these qualities as relatively constant factors, we collected data related to: A. subject variables: sex; occupational identity (lawyers, journalists, physicians, psychoanalysts, technicians, nurses, artists and performers); chronological age (24 to 74); and personality type; B. four con-

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

ditions, in terms of separation in time and space, of experimenter from the subject in the tank; and C. two alternatives in reporting: immediately following the run, and during the run itself. (Subjects were permitted free choice between alternative conditions of experimenter distantiation, and of reporting.)

Certain considerations seemed relevant at this level, and were observed rigidly. The experimenter and his assistants prepared for the observer role by first using themselves as subjects; the subject was familiarized thoroughly with the experimental conditions by a step-wise series of time-limited runs prior to definitive endurance runs. The identity, and longest times of all subjects were known only to the experimenter.

Strenuous efforts were made to eliminate any suggestion to the subject by project personnel of what might or might not occur. Spontaneous reporting by the subject was encouraged and all queries by the experimenter were general and open-ended in the interviews between the subject and the experimenter. Naturally, the anonymity of each subject and the confidentiality of all personal data were made explicit to the subject and were scrupulously observed. Permission to limit or eliminate participation at any time without prejudice, was specifically granted each subject in advance.

Together, these measures resulted in a state described afterwards by one subject as, "an extremely monotonous state of massive comfort, with built-in confidence and security, yet with an air of fascinating mystery about the outcome."

FINDINGS

Detailed consideration of the manifold aspects of the extensive data is obviously not possible here, and many of the observations lend themselves poorly or not at all to quantitative reporting. A portion of the data are here presented to two ways: first, a condensed, narrative account, much of it in the subject's own words; second, a summary of selected data from many experimental runs by many subjects.

FINDINGS IN ONE SUBJECT

The following is a chronological report from a tape recording of the experience of a 29-year-old married male, college-trained journalist, who desired to write a feature story from first-hand experience, and who felt that the experience might resemble that of the first astronaut.

The familiarization run occurred three days prior to his experimental run and only slightly dampened his enthusiasm, despite the fact that just prior to the run, he unexpectedly panicked when he placed the mask over his head (a thing he previously had done a number of times without undue anxiety). He had to remove and replace the head mask several times before he felt comfortable enough to enter the tank. The experimenter who was standing by, was mildly surprised and reminded the subject that he could stop participation if he wished. The subject declined, however, and once the run started, he continued to its pre-set limit of 3 hours, with the observer in the outside, monitoring position. The familiarization run revealed that the mask leaked badly, and that the tank water at 92°F. was too cold, resulting in chilling. The subject experienced headache and severe stomach cramps, had a vivid fantasy of shopping for a private plane, and was startled to learn that only he had heard dogs barking at one point. He reported afterwards that "that was more peace and quiet than I've ever had by myself," and that he felt unusually calm and relaxed for the remainder of the day. He viewed the total experience as "enjoyable."

EXPERIMENTAL RUN

The subject appeared at the laboratory at 8 a.m. on a Saturday, with a day free of obligations or plans until 7 p.m. His vital signs were normal, and a half-hour saw him launched on his run, with a comfortable mask which leaked considerably less than the one he had used before, yet proved to require self-bailing every half to three-quarters of an hour. He denied anxiety about the mask and expressed great puzzlement as to what had caused his previous panic. With the observation that "the knowledge you are right across that wall impairs the feeling of being alone," he dismissed the experimenter from the immediate scene to a point where he would be available by telephone from 10 minutes away. The subject revealed that he was determined to use his time this day to prepare in his mind an important report and a budget, both due within a week. He elected to report his experience as

it occurred, with tape recorder running. "Everything," he said, "pointed to a 'good' run," and he anticipated a pleasant time.

His first half-hour was spent motionlessly, except for a monologue of his everyday thoughts and concerns. These were: anxiety over a strange and entirely unusual somnambulistic act of his wife's two nights before; guilt over disappointing his boy's expectations of him on that day; curiosity about an unexpected letter from a girl friend unheard from for years; philosophizing about life, and over "What it all means"; pleasure and pride in his job. ("I've got a front row seat at the greatest show in the world!") ; irritation over and disapproval of the attitudes and behavior of the younger generation of journalists. Following each shift of thought, he would digress briefly into some childhood memory associatively connected. In listening to this tape later, the experimenter was forcibly struck by a curious quality about each remark; namely, that each was expressed in ambiguous language that, on a different level, invariably could be construed as a comment on a popular fear about the sensory isolation experience. For the above series, this went as follows: embarrassment at doing something slightly ridiculous or crazy; anxiety over loss of contact with firm ground; regret over failure to establish a good communication link with another in advance; concern over being brain-washed; frustration in the effort to derive some deeper meaning out of the apparently meaningless and ambiguous situation (*i.e.*, the structureless experimental sensory isolation situation) and a turning to the recollection of rich personal sensory experiences enjoyed in the past.

In the second hour his comments concerned his self-thwarted, increasing urgency for "exercise" and physical activity; amazement at his lack of appetite for a cigarette; his state of utter loneliness and solitude, save for "my very real companions, my thoughts and memories"; compassion for the little space-monkey, Sam, who received only half an apple and a glass of water for his dinner after his historic trip 55 miles into space; thoughts of food and sudden, intense hunger pangs.

He whistled, and then sang the refrain from a popular tune which went, "I'll never get rid of that ---, ---, ---!" Apparently he dropped off into a short (less than two minutes) nap; he woke with a start and the eerie feeling he had just been "out of this world," and with a very vivid, "long" dream, which he struggled to recall. He succeeded in recalling only a part—"a sawdust cream cone."

In the third hour he questioned and then

asserted he heard the very faint sound of water trickling (the tape records the sound); asserted he heard dogs barking (not present on the tape); and commented on a "crackling sound" (unable to verify from the tape). At intervals he sang, increasingly louder, the refrain from a slightly obscene ditty which began, "Roll me over—."

Increasingly strong impulses to action came: "I had an urge to make like a porpoise, but those darned hoses (air supply) won't let me!" Briefly, he seemed to be in quite an ebullient, elated mood. Suddenly, he plunged into grief and tears with the expressed thought, "How many people really think about what it's all about? How many people ever, ever think—just once—about love?"

Within seconds, the depressed mood vanished and he was again joking, whistling, and laughing. A make-believe dialogue ensued, as he asked, anxiously, "Joe, what do you do when your engine quits at 200 feet?," and replied, in a peal of laughter, "You land the sonofabitch!"

Immediately following, his tone shifted and he uttered an angry command; "You voice! Keep quiet up there! Quiet!" He, himself, obeyed, and was silent, but only briefly. He hummed. He sang. He sighed deeply. He yawned. He seemed unutterably bored.

His thoughts turned to his plan to compose his report and his budget, and the belated recognition he had not even begun to accomplish this. In a half-hearted explanation to himself, he said "I just allowed my thoughts to drift." Futility and resignation hung from his tone of voice. He then remarked briskly, "I seem kind of wide awake. I ought to get out!" For a period following this, there was more singing, more humming. Then, "I don't know, but it seems like I heard voices. Somewhere. Male voices. Men's voices. Too bad! (laughter) It should have been a bunch of dollies!" He laughed again. More singing came.

In a tone of extreme annoyance, he blurted out, "I might just as well be Sam, for all I can be or do or think or hear or be or smell or taste!"

Over the next 10 minutes he argued himself into the position that he was "just wasting time." "After all, I feel fine." "This is ridiculous" (here he referred to his being a grown man bobbing around in the dark in a tank of water in a hole under the hospital). "Besides" he added, "This run isn't producing any data for the doctor, anyway!"

Again, he commented and questioned whether he really was hearing "some noises."

Abruptly, he pulled off the mask and left the tank.

Over the 4½ hours of his run, his longest mute period had been less than 6 minutes.

In the observer room, he dried, dressed, took his pulse (80), his temperature (98.2°) and respiration (16). He guessed that it was now 12:35, and was elated to discover, on uncovering the clock, that it was 1:00 P.M. He picked up the interview card, and dictated into the recorder his response to the first instruction: Give a spontaneous account of the run.

This one was a calmer thing, from the beginning to the very end. I don't know if you got any material out of it you can really use. I enjoyed this one to a degree. I have no specific recollections, except that I seemed to doze quite a bit at first. I don't believe I dictated as much as last time. I don't feel as subdued as after my first run. I feel like I'd like to go out and hunt bear! I feel more exhilarated, refreshed, and rested than I did after that first one. I'm sorry, I don't have a lot to say. [Apologetically], I noticed I thought a lot about women this time.

In response to the question, why terminate now?, he replied,

I had the feeling there were some things I ought to be doing . . . I don't know now, though, what they were . . . I felt like I was "coming to," and I was getting bored, and it just didn't seem like I should stay. That's why I quit now.

Coincidentally, the experimenter returned to the scene at this point, intending to check the operation of the automatic equipment in the outer chamber, and discovered the subject busily interviewing himself. The experimenter remained, listening passively, while the subject continued his report and occasionally injected, or replied to a question. He noted that the subject seemed unusually buoyant, gay, and energetic. He was amazed to hear the subject calmly report that on several occasions he had seen a brilliant white light, that "looked like the sun through a peep-hole," and once had seen an inverted "V" in brilliant blue and white flame moving through dark space toward him. This occurred about half way through the run. Shortly after this he ex-

perienced an "extremely strong" and persistent feeling that "someone," identified as friendly, had entered the chamber and was "in the room with me." After these and several similar accounts of experiences in isolation, he apologized, "I have so little to offer this time."

As he neared the end of the interview, he waxed increasingly angry. These feelings reached a climax with the vehement assertion, "I honestly believe, if you put a person in there, just kept him and fed him by vein, he'd just flat die!"

One further observation by the subject deserves mention. He commented on what was to him a curious, paradoxical fact. Although he could visualize his complete budget sheet with photographic clarity in his mind's eye (a feat he is incapable of in everyday life) he simply could not "hold on to it and work with it." "Everything I thought of came to mind much more vividly than it would outside, but I simply could not concentrate." In addition, he noted that certain mental images experienced on a previous trial run could be recalled as freshly as if they had just happened.

The post-run interview lasted an hour and a half, during which time he lit one cigarette, but took only one or two puffs (he is almost a chain-smoker in everyday life). He also ignored a proffered cup of coffee, which turned cold on the table before him—a thing he ordinarily would never have allowed.

His buoyant mood and unaccustomed energy persisted throughout the day, and he reported that "nothing else unusual—nothing at all" had occurred when he was queried a week later. However, a colleague of the experimenter's happened to hear him reading a newscast on the evening following the day of the run, and noted that the subject, usually a facile and accomplished speaker, hesitated momentarily and stumbled in pronouncing the words "water" and "Medical Center," but gave no indication of awareness that he did so.

The news feature which he planned remained uncompleted 4 months later.

FINDINGS IN GENERAL

Results under the two alternatives of reporting (*i.e.*, retrospective or both simul-

taneous and retrospective reporting) permit the observation that simultaneous reporting generally was much richer in detail and appeared to inhibit less the revelation of marked deviations from usual feeling states, imagery, and thought content. Retrospective accounts, however, were most revealing. Put another way, the healthy ego seemed to possess an incredible degree of ability to utilize repression and other defensive mechanisms that drastically limited the full reporting of experience. With only an occasional exception, persons having had considerable subjective experience of analytic-type psychotherapy consistently reported fuller and less distorted retrospective accounts of what is called "ego-alien" or "primary process" experience. Subjects with experience as analysts reported even more of this experience and with even less distortion.

No generalizations are possible as yet regarding the effects of temporal and spatial distantiation between subject and experimenter. It was obvious that anxieties of both were significant in determining what was requested and allowed, but other factors also are involved.

For many reasons, the reporting of findings in the area of mental imagery is exceptionally difficult, yet one of the most dramatic findings of these experiments concerns this very area. Mental imagery phenomena, broadly conceived, invariably were present in every run of every subject in our series, although conditions of reporting dictated that in some instances they were inferential, rather than direct. The variety of these experiences defies classification and description. For example, consider how one would classify this: "I strongly felt that I was stirring with my left leg, and it was a spoon in an iced tea glass, just going round and round. I 'came to' with a start to realize that my leg *was* going round and round." By contrast, the following seems easy to classify: "I suddenly saw in the darkness before me a field of golden toadstools, with the sunlight brightly reflected from the stem of one." The latter experience might be described as purely visual, three dimensional, and in color. The subject was able to paint a picture of what she saw. A fuller description of data on

mental imagery soon will be available elsewhere(12).

Under the extreme conditions of our experiment, clear limits of what might be expected (for example, what might be heard) were non-existent. Two physician subjects independently reported having been startled to hear, without benefit of stethoscope, their own heart sounds at ear-filling intensity. One of them reported having heard repeatedly the snapping sound of his own aortic cusps closing at the end of each systole. A third physician subject reported in awe that for the first and only time of his life he heard the gliding sound made by moving his large joints. Such reports, if verified, raise the interesting question of whether they are to be regarded as instances of enhanced sensory acuity, lowering of sensory thresholds, or enhanced ability to fix attention.

There was a general tendency, following a run, for pulse, respiratory rate and blood pressure to drop moderately, and for body temperature to rise slightly, although exceptions were noted. Nine of the 12 subjects made runs exceeding 180 minutes, but none exceeded 400 minutes. Within this range, post-exposure feeling states varied both between subjects, and for the same subject between runs. We saw marked calmness and extreme irritability, buoyancy and lethargy, vigilance and somnolence. Most frequently we observed a peculiar, mixed state characterized by calm, clear mental vigilance, coupled with lethargy, muscular relaxation and a decided disinclination for exercise, but without any sense or sign of fatigue.

DISCUSSION

The single run reported here is not atypical. There are wide individual variations in specific mental content, but much fewer variations in form and sequence of events.

When one takes out light and sound, one perforce puts in darkness and silence; when one takes out change and structure, one puts in monotony and non-structure. When one takes away gravity, a state of weightlessness obtains. Thus, every "negative" state has "positive" consequences. In terms of these consequences, the former (or

negative) state may be far more potent, regardless of how much physical energy input or stimulus is denied. As a matter of fact, for a conscious human, the *absolute* elimination of *any* sensory input, save for special modalities within very narrow limits (e.g., visible light), is impossible, and can be approached only asymptotically.

CONCLUSIONS

A feasible and effective method has been described for studying a wide range of psychophysiological phenomena under circumstances permitting exceptionally effective isolation and demonstration of discrete elements in the complicated, interconnected patterns and sequences underlying even the simplest human act or experience.

A number of hypotheses relating to very fundamental issues can be erected from these observations and can be subjected to experimental testing. In due course, such experiments may contribute to a more adequate understanding of human behavior.

DISCUSSION

JOHN C. LILLY, M.D. (St. Thomas, Virgin Islands).—The importance of this work seems to lie, not in its testing and extension of research on isolation and confinement in water which I began in 1954, but in the fact that a group is doing profound isolation and confinement in a water immersion situation. It has been my impression, and my published opinion, that this kind of isolation, in which all possible sensory inputs and information exchanges with the physical and social surroundings are reduced towards zero, will be a fertile source of knowledge of the human mind in a short term and in a long term sense.

When this work was initially presented in 1956 in the *Psychiatric Research Reports No. 5* (Lilly) it was inadvertently linked up with a negative aura conditioned by the brain washing milieu in which similar studies were being carried out in the laboratory of Dr. Donald Hebb. It also suffered from being born in an atmosphere of research on mental illness. I do not feel that either of these bedfellows can benefit except by products from the research. The research itself should be on a much broader biological and psychological basis. To put it very simply, our curiosity about the functioning of human minds can be satisfied and intrigued by these techniques as by no others. The amount of information which can be, and is, generated by each subject in these experiments in a few hours can be mountainous and overwhelming, even as it can be by a freely associating person lying on a couch. The advantage of the watertank over the couch is that the conditions are more extremely isolating and there is a

greater degree of true aloneness achievable in the tank. For healthy subjects this has the distinct advantage of lessening the feeling of someone looking over one's shoulder watching one's thinking processes. One can, as it were, really be free of supervision, the necessity of exchanges and the necessity of organization of one's thinking for the purposes and activities of others.

The truly individual aloneness achievable by this method allows one to find out the following basic facts :

1. The human mind is not a solipsistic cesspool of circuitous internal feedbacks. "Pure thought thinking of itself" is not the net result of such work.

2. The human mind in this situation can be seen to be a true source of continuous new information, some recorded in the past but inevitably generating new relationships interwoven with information recently derived from social realities and from the anticipated future.

3. Demonstrations of the portions of the human psyche which are not under the immediate control of one's own self are shown in a dramatic and immediate fashion to those who are ready to see them.

4. In my own experience, and apparently in that of some others, who have been through these experiences (and similar ones in prisons, small sailing vessels and polar huts), one gains an increased awareness of, and a willingness to move with, power, speed and integrity along the lines of one's life situation along which one really and truly wishes to move. The long term effects of repeated satisfactory exposures to these extreme conditions in several cases have been quite rewarding.

In contrast to most other isolation experiments, there seems to be an underlying thread of a reward balance in the reward and punishment account book in the immersion type experiments. Once a satisfying solution to the technical matters is provided for the subject, I found, as have Shurley and Bennett, that the subjects want to repeat their exposures and seek out opportunities to do so. One may ask if addiction might develop. My answer is No, eventually one becomes weaned from such artificial aids for exploring one's mind. In my experience practically everyone who has been through this has been very much impressed with the experience. No one has yet called it trivial.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

THE EFFECT OF R-1625 (HALOPERIDOL) IN MENTAL SYNDROMES: A MULTIBLIND STUDY

H. AZIMA, M.D., H. DUROST, M.D., AND DOROTHY ARTHURS, R.N.¹

Haloperidol² was recently introduced as a "major" non-phenothiazine neuroleptic agent.³ It is chemically not related to any known tranquilizers and is a 4-fluoro-4,1-(4-hydroxy-4-(4'-chloro)-phenylpiperidino)-butyrophenone.

Haloperidol's therapeutic efficacy was tested in a research setting consisting of a "pharmacotherapeutically blind unit," i.e., a hospital service where all drugs are given at random and used blindly, i.e., without the knowledge of the service team made up of one intern, 2 assistant residents, one resident, one psychologist, 2-4 nurses, one social worker and one occupational therapist. An average of 4 drugs and one placebo are tried on this unit at any given time. The final assessment is through the pooling of the opinions of the different members of the team. Because of the use of this "pharmacotherapeutically blind" routine and blind assessment by "multiple observers," the regime is called "multi-blind." The degree of therapeutic efficacy is assessed through a simple rating scale graded from 0 to 4, consisting of two parts (behavioral and experiential) and designed mainly to show the changes in the target symptoms. Only "marked" to "moderate" improvements are taken as significant.

Forty-two patients received haloperidol and 42 placebo. Haloperidol receiving patients consisted of 23 neurotics (5 anxiety hysterics, 3 chronic anxiety states, 2 obsessions, 10 mixed neuroses, 2 depression plus

anxiety, and one character disorder) and 19 schizophrenics (3 simple, 1 catatonic, 14 paranoid and one schizoaffective). Placebo receiving patients consisted of 27 neurotics (1 anxiety hysteria, 4 chronic anxiety states, 4 obsessions, 11 mixed neuroses, 4 depression with anxiety, 2 hypochondriasis, and one character disorder) and 15 schizophrenics (1 simple, 1 catatonic, 12 paranoids and one schizoaffective). There were 27 males and 15 females with an average age of 40 in the haloperidol group and 25 males and 17 females with an average age of 38 in the placebo group.

All patients received the drugs orally with an average haloperidol dose of 6 mgm. daily (maximum 24 and minimum 2 mgm.) with an average duration of 3 weeks (maximum 3 months, minimum 10 days). The regime of drug and placebo administration was that of "gradual increase."

Comparison of the results in drug and placebo groups revealed 38% marked to moderate improvement in haloperidol treated patients, in contrast to 11.8% in placebo treated patients. Out of 23 neurotics treated with haloperidol, 6 (2 anxiety hysterics, one chronic anxiety state, and 3 mixed neurotics) showed moderate and one anxiety hysterics marked improvement; while in 27 neurotic patients treated with placebo, 4 (1 anxiety hysteric, 1 chronic anxiety state and 2 mixed neurotics) showed moderate improvement. Out of 19 schizophrenics treated with haloperidol, 4 showed marked and 5 moderate improvement; while in 15 schizophrenics treated with placebo only one patient showed moderate improvement.

Side effects were relatively numerous and disturbing to the patients. These consisted mainly of extrapyramidal symptoms: body

idity and facial muscle tension in 15, euphoric crises in 2 and generalized tremor and jitteriness in 10. In addition, I. symptoms such as vomiting, nausea, anorexia, etc. were noted in 7 patients, hypotension in 11, weakness and syncope in 9, extreme fatigue and sleepiness in 7, drowsiness in 5, blurred vision in 1 and dysuria in 1 patient. The appearance of extrapyramidal symptoms were directly related to the dosage. Beyond 20 mgm. per day, almost all patients developed these

symptoms. Changes in biochemical studies done once a week (liver function, blood count, transaminase and urine analysis) were minimal.

The final impression was that haloperidol was a moderately potent neuroleptic, much less effective than claimed by European authors, with numerous side effects. However, its greater potency in schizophrenic states indicated the necessity of further studies in this area.

PRELIMINARY REPORT ON MELLARIL IN EPILEPSY

MARIE M. FRAIN, M.D.¹

After concluding a pilot study in which a ward of 50 psychotic geriatric patients became more manageable and less disturbed within a month using Mellaril,² a major project was started for evaluation of its use in severely disturbed epileptics with psychoses. Comparative charts on seizures, behavior, and personality during three time spans were selected for intensive study.

NO TRANQUILIZER PERIOD (1952-1954)

Of the 70 white females chosen, all but 22 had been in the hospital 10 years or more. Behavioral characteristics: belligerence, unpredictability, unkemptness and uncooperativeness. Phenobarbital gr $\overline{150}$ H.S. constituted the only sedative. Many of the individuals required wet packs, cuffs and strait jackets. Wards were noisy and disruptive.

THORAZINE PERIOD (1958-1960)

This same group was given chlorpromazine, 300 to 600 mg. in 24 hours, depending on individual needs. All but 12 (82%) definitely improved physically and mentally. Many received ground privileges, some participated in occupational therapies, and many enjoyed recreation hall facilities. Wards became quieter and patients more easily managed. Wet packs were discontinued and strait jackets and cuffs were discarded.

MELLARIL PERIOD (MARCH 1, 1960 TO THE PRESENT)

Mellaril was begun on the same group with no interim rest period, since without tranquilization, violence would have recurred. The usual 100 mg. t.i.d. dosage of Mellaril was increased for 10 patients to the amount of 150 or 200 mg. t.i.d. at the end of 3 weeks. Rarely have other changes been needed and after 6 months the whole group seem to be adjusting nicely.

RESULTS

All were disturbed while the only sedative was phenobarbital.

TABLE 1
THIORIDAZINE SIDE EFFECTS

Symptoms	Number of Patients
Dry Mouth	1
Extrapyramidal	0
Drowsiness	With dose 400 mg. or more.
Change in Blood Pressure	0
Dermatitis	0
Nausea (slight)	5
Lactation	0
Edema	0
Blood Dyscrasia	0
Retinitis *	0
Jaundice	0

¹ Wyoming State Hospital, Evanston, Wy.

² Sandoz & Company, Hanover, N. J.

* Ophthalmologist cooperated for eye examinations.

Fifty-eight patients improved on thiorazine. Seventy out of 70 were maintained on Mellaril with 61 (87%) receiving added benefit over and above what thiorazine was able to do. Side effects were negligible. (Table 1.)

CONCLUSIONS

1. Mellaril is a smooth acting, efficient therapeutic agent in the treatment of the psychotic patient.

2. Nausea is not masked.

3. Side effects in this study have been negligible.

4. Mellaril proceeds to aid psychotics with their behavioral problems over and beyond what thiorazine is able to do.

5. Fewer accidents reported during the 6 month period.

6. Relatives visit chronic epileptics more often and receive greater pleasure from visiting, since all patients have been maintained, improved, or markedly improved.³

³ Comparative seizure charts will, we hope, give valuable further information at the year's end. Laboratory results will also be closely evaluated.

TRIFLUOPERAZINE AND TRANLYCYPROMINE IN CHRONIC REFRACTORY SCHIZOPHRENICS

WALTER KRUSE, M.D.¹

In previous reports(1, 2), we have discussed the usefulness of trifluoperazine in treating schizophrenics and particularly in controlling hallucinations. For the present study we selected 40 chronic schizophrenic women who had not improved on trifluoperazine or any of the many other neuroleptics they had received. These were truly the "hardcore" patients; their average length of hospitalization was 12 years, during which time they had received virtually every kind of therapy.

The most prevalent symptoms in these patients were apathy, withdrawal, lassitude, psychomotor retardation, and inability to concentrate. With this symptom pattern in mind, we began adding imipramine to the trifluoperazine already being given. Noting no response, we then tried several monoamine-oxidase inhibitors in succession. The most promising results were seen with a combination of trifluoperazine and tranlycypromine,² a non-hydrazine MAO inhibitor. Dosage was individualized for each patient. Most patients were already being maintained on trifluoperazine, 10-15 mg., b.i.d., and tranlycypromine was then added in doses of 10-30 mg. daily. In 12 patients

who had been well-maintained on chlorpromazine, the MAO inhibitor was merely added to the established regimen. Duration of the study was 3 months.

RESULTS

Nine of the 40 patients were considered much improved at the end of the study. One of the 9 was receiving chlorpromazine, 200 mg. b.i.d., and tranlycypromine, 20 mg. b.i.d.; the other 8 were receiving trifluoperazine and tranlycypromine. Although 9 out of 40 is a small percentage, it must be kept in mind that these were among the most refractory patients in the hospital, and any improvement is notable in view of the lack of response to all previous therapies. The remaining 31 patients showed no better response to this combination than to any previous treatment.

DISCUSSION

The 9 patients who benefited showed their improvement by manifesting more interest in their surroundings and an increase in psychomotor activity where it had been previously lacking. Two of the 9 had been semistuporous before treatment.

There was a marked decrease in apathy and lassitude and an increase in ability to concentrate and make decisions. Improvement came about slowly in most cases, becoming gradually more apparent within the

¹ Chief of Female Service, Danvers State Hospital, Hathorne, Mass. Present address: Bundiswung 8, Westerland/Sylt, West Germany.

² The drugs used in this study were provided by Smith Kline & French Labs.

second and third month. In 3 patients in whom auditory hallucinations and delusions were major symptoms, these symptoms were greatly lessened or entirely relieved.

Since there was little symptomatic difference between the patients who responded and the majority who did not, no reason is apparent as to why the combination of trifluoperazine-tranlycypromine worked in some cases but not in others. It is encourag-

ing, however, that 9 of these seemingly hopeless patients did show a notable improvement. Further work on this combination is needed, but it is our impression that these drugs warrant a trial in the chronic refractory schizophrenic patient.

METHYLPHENIDATE INTERVIEWS IN PSYCHOTHERAPY

GEORGE A. ROGERS, M.D.¹

Oral methylphenidate² to enhance psychotherapy was studied in 16 outpatients for a year. It has been helpful intravenously in alcoholics (2, 4).

A double-blind procedure was used. Each interview was rated in 3 areas : emotional expression, verbalization, and constructiveness.

Six months was spent in the study of the reaction of patients to the drug prior to the study. The general nature of the study was explained to the patients beforehand. A 10 mg. tablet was given one hour before the appointment on an empty stomach. The total dosage per interview was then adjusted to 40, 60 or 80 mg. one to one-and-a-half hours prior to the interview, depending upon the patient's reaction.

This study was more effective than most double-blind studies, since a physiologically effective dose was insured with each patient. The routine administration made any detectable physiologic effect inconspicuous. The experiment indicated that the drug would be of greater use when used selectively rather than routinely.

Experience with the drug emphasized the variability of its reaction, particularly with psychiatric patients.

1. Doses ranged from 10 mg. to 80 mg. In psychotics, even 10 mg. was extremely disturbing. In withdrawn and unemotional

patients, 60 to 80 mg. had little discernible effect.

2. Two patients complained of a rebound depressive effect 3 to 4 hours after taking the drug. One patient had an attack of suffocating feeling similar to globus hystericus on 60 mg. with panic. This was relieved by intramuscular chlorpromazine.

3. One patient subject to seizures about once yearly had a severe headache the remainder of the day when he took 10 mg. of methylphenidate. Another patient with migraine had a one-sided headache after taking 60 mg. It would, therefore, appear that in the dosage used methylphenidate has a slight tendency to be a convulsant.

4. One patient had a recurrence of partial dissociation on the occasions when he took the drug.

5. There were 4 instances in which patients attributed effects to the drug which later appeared to be definitely psychological.

There were 3 groups of results : a definite helpful effect ; a definite harmful effect ; and little appreciable difference.

In two obsessive compulsive and one phobic patient, the drug was unequivocally helpful. The same was true for two patients who had psycho-physiologic reactions as depressive equivalents. These patients had illnesses of long standing. In psychotics and pre-psychotics the drug seemed definitely contraindicated, not only because of the anxiety it provoked, but because even where the verbalization or emotion was in-

¹ Gloucester County Guidance Center, Woodbury, N. J.

² Study conducted under a research grant from Ciba Pharmaceutical Products, Inc., Summit, N. J. who supplied methylphenidate as Ritalin.

creased, the constructiveness or the usefulness of the drug interviews was definitely less. Acute anxiety reactions seemed to be aggravated by the use of the drug. Straight depressions did not benefit materially from the use of this drug. There was a difference in the subjective effect of the drug between those who were helped and those who were hindered. The patients who were helped generally found the drug pleasant and felt elated and high. Those who were hindered complained of an unpleasant production of tension. The medication was not helpful in poorly motivated patients.

The difference between the patients who were helped and those who were not was whether the illness was in a state of flux or not.

The study supplied a new insight into the problems inherent in the "double-blind" method(6). Particularly with drugs it is necessary to establish the dose of the medicine which will be physiologically effective in each test subject. In addition, it must be kept in mind that some drugs suppress at one dosage and stimulate at another. The level for these effects varies from person to person and from one occasion to another.

IMIPRAMINE TREATMENT

MICHAEL J. KEITH, M.D.¹

To follow-up my previous clinical note on experience with several "anti-depressant" drugs in private psychiatric practice :

I have abandoned the use of the MAO inhibitors, as I have noted no therapeutic response, and have continued to use imipramine on a somewhat larger scale. There appears to be a variable anti-depressant action associated with imipramine in doses of 75-300 mgm. a day. This is not consistent, and it is difficult to predict which patients will respond. My impression is that in severe agitated depressions the response is minimal. Also, depressions marked by extreme withdrawal and anergia show poor response unless an amphetamine-type drug is given concurrently.

My present practice is to prescribe imi-

SUMMARY

1. The use of oral methylphenidate to potentiate interviews in 16 office psychotherapy patients was studied for a period of one year. Results indicate that in patients with fixed neurotic processes it can speed the therapeutic progress.

2. The drug gave no physical complications in 16 healthy subjects in doses that were two to four times that ordinarily prescribed. Dosages ranged from 40 to 80 mg. orally per dose.

pramine 25 mgm. q.i.d., combined with a milder ataraxic, or if agitation is marked, a phenothiazine derivative. If the patient is anergic, an amphetamine-type drug is administered. Concurrently, bedtime hypnotics are used if required. The dosage of imipramine is raised as needed to a maximum of 200 mgm. per day.

The time of response appears to be variable from 2 days to about 2 weeks. The manic-depressive patient reported in my previous paper has responded to imipramine on three occasions within 2 days when combined with promazine.

An interesting complication of imipramine therapy has been noted in 5 male patients in the 50-65 year age group. In 4 of these, complete urinary retention took place while on a dose of 75-100 mgm. per

¹ 745 Graydon Ave., Norfolk, Va.

day. In another patient some difficulty in voiding took place. All these patients had moderate prostatic enlargement. On one of them a transurethral resection was done; the other patients either had the dosage lowered, or a Foley catheter was inserted to ameliorate the symptom.

It is not possible to fully implicate the imipramine, as, of course, many of these patients were receiving other medication which have effects on the autonomic nerv-

ous system (such as the phenothiazines and in one case, probanthine). However, it is well worth while to bear this in mind and treat quite seriously any complaint of difficulty in voiding in a middle-aged male on imipramine.

In summary, imipramine appears to be a potentially useful drug in the treatment of depression, but its action is unpredictable and apparently is not highly effective in the more severe cases.

IMIPRAMINE HYDROCHLORIDE (TOFRANIL) AND ENURESIS

R. E. G. MacLEAN, M.B., B.S., D.P.M.¹

In the course of studying the application of imipramine hydrochloride (Tofranil) to depressive states encountered in adults attending the Observatory Clinic, a mixed adult outpatient and child guidance clinic under the Victorian Mental Hygiene Authority, the senior psychologist (Mr. Hugh Esson) suggested that this drug might be of use in the management of enuresis in children. It was tried, and, possibly as a result of the difficulty in initiating micturition which is reported as a side-effect of the drug by a proportion of adult depressive patients, it has had a marked symptomatic effect in doses of 25 to 50 mgm. each evening.

The smaller dose is effective in the majority of enuretic children under 12, the larger in those older, in ensuring that most nights are dry; even in those consistently wetting. Inert tablets resembling the genu-

ine ones have not yet been used in a controlled study, and no conditioning to dryness such as frequently follows treatment with electrical awakening apparatus has been noted, for children relapse as soon as the drug is withdrawn.

Nevertheless it is useful to have at one's service a drug which can, for example, mitigate the severity of parental attitudes by removing, while this treatment continues, a main excuse for aggression. Again it is useful to be able to place in a child's hands a means of allowing his attendance at Scout, Cadet, Church, *etc.*, camps free from his former fear of wetting.

The medical staff of this Clinic are continuing this study, but it is encouraging enough to warrant this brief note in the hope that wider application as a result might lead to fuller evaluation, and in the meantime to more comfortable nights for some of the ashamed incontinent in our care.

A STUDY WITH NORETHANDROLONE (NILEVAR)¹ IN A MENTAL HOSPITAL ON PATIENTS WITH BOWEL AND BLADDER INCONTINENCE

SOL SHERMAN, M.D.²

Inability of physicians to treat effectively bowel and bladder incontinence due to mental and emotional factors poses a serious problem. Initial studies by Saunders

and Drill of a group of anabolic steroids showed(1) that norethandrolone (Nilevar) produced an increase in weight of the levator ani muscles of castrated rats, and at the same time exhibited minimal androgenic effects. Vlavianos and Fink studied

¹ Nilevar was supplied by G. D. Searle & Co.

² Metropolitan State Hospital, Waltham, Mass.

(2) 11 male patients in the first clinical trial of norethandrolone for the control of bowel and bladder incontinence. They found norethandrolone effective within one week in stopping wetting and soiling in 6 of their patients. A follow-up study by Vaisberg, Michael and Saunders showed (3) that norethandrolone achieved excellent clinical results in 7 of 9 elderly patients treated for bladder and bowel incontinence.

In the present study 13 of the most severely incontinent patients at the Metropolitan State Hospital were placed on Norethandrolone. The ages of these patients ranged from 31 to 80 years. Eight of them had schizophrenia (2 catatonic, 2 hebephrenic, 1 paranoid, 2 of chronic undifferentiated type and one other unspecified), 2 had Alzheimer's disease, one had syphilitic meningoencephalitis and one had Korsakov's syndrome. These patients had been hospitalized for periods of 6 months to 29 years.

The severity of the problem of incontinence was judged by whether the patient soiled 1 or 2 times daily, 3 or 4 times daily, 5 or more times daily, or continually. The severity of the condition was rated by the numerals, I, II, III and IV, respectively; initially, two patients were rated as I, 5 as II, 3 as III and 3 as IV.

The patients received norethandrolone for periods of 8 days to 5 months. They were given 10 mg. by mouth t.i.d. Following initial norethandrolone therapy, the drug was discontinued simultaneously in all patients with no further medication administered unless incontinence returned.

Initially 7 patients showed excellent improvement, 2 good improvement, 2 fair improvement and in 2 the condition was unchanged. Two patients whose incontinence was intractable were subsequently given 50 mg. of norethandrolone intramuscularly, followed by no medication for one week, then the injections of 50 mg. were

repeated, but again without any clinical improvement.

Supplementary norethandrolone therapy was required in 5 patients. At this point dosage was individualized according to patients' needs. Three of these patients had fair results, receiving 10 mg. of norethandrolone t.i.d., but two patients did not respond to this dosage and were given 20 mg. t.i.d. Both patients failed to respond to the higher dosage. The one patient of the original 13 continued to refuse to take the medication and was dropped from the study after approximately two months of therapy.

CONCLUSION

Norethandrolone was effective in controlling bowel and bladder incontinence in 10 of 13 patients who had been hospitalized for periods of from 6 months to 29 years. The most severely incontinent patients at the hospital were chosen for this study.

Upon conclusion of the study the improvement in 6 patients was excellent, in 1 good, in 3 fair improvement, in 2 it was unchanged, and one patient was dropped from the study because he refused to take the medication. A daily dose of 30 mg. by mouth was effective in most instances. No side effects were noted at any time during norethandrolone therapy. The mechanism by which norethandrolone exerts its anabolic action is not fully understood, and further studies in this area are planned. The results of this study are in agreement with those of Vaisberg and his co-workers and Vlavianos and his associates.

CASE REPORTS

THE GAMBLER AND HIS LOVE¹

IAGO GALDSTON, M.D.²

The psychiatrist, unlike the clinician, does not have either ample means or frequent opportunities for testing out his postulations as to the aetiology, the basic pathology, and the therapeutic handling of a given case. Psychiatry has nothing that equals in specific relatedness the tuberculin, the Schick, or the sugar tolerance test. Psychiatry lacks the equivalents of Koch's postulates, so determinate in establishing the authenticity of the causative agents of the infectious diseases. It is therefore rewarding to come upon an instance wherein the patient's own life experience confirms, at a later time, the validity of the formulations, postulated earlier, to account for the dynamics of his psychopathology.

It is such an experience that I wish to detail here. I initially described the patient in a paper published in *Mental Hygiene*, in October, 1951. The title of that paper was "The Psychodynamics of the Triad, Alcoholism, Gambling, and Superstition." The gambler was one of the "triad." Here I will describe him only sketchily, leaving out many details of his anamnestic history. They are not really relevant to the substance of this presentation.

The patient was, as he is today, an habitual and compulsive gambler. He did not in the first instance come for therapy because of his gambling; on the contrary he accepted gambling as a normal and even desirable component of his life pattern. His complaint was of a mild and, as it proved, a transient sense of depersonalization. It was associated with and had been precipitated by, the development of a psychotic reaction in his older brother. The patient had identified with and had introjected his sick brother.

The patient was an almost completely illiterate Jew, 44 years of age, married, and the father of two children. He was successful in business, shrewd, intelligent, and wealthy. He gambled consistently, and had done so since he was 12 years of age. He was in no sense a professional gambler. He gambled, as he phrased it, because he *had* to gamble. It temporarily relieved him of some kind of tension, the nature of which he did not understand and could not describe. I was intrigued by what he termed his "tension," and endeavored to trace its aetiology, as well as to fathom the mechanism by which he gained relief in gambling.

Here I will only present my conclusions as to the aetiology of his tension, without citing the anamnestic data from which they were derived. These data can be found in the earlier paper.

The patient had suffered early and severe deprivations in his affect relations with his parents. He was born in a small village in Poland, and grew up in poverty and squalor. His father was early separated from his mother and lived in a distant village. The patient was apprenticed to a shoemaker at the age of 7. From that age until he married, he had had no home. He was thus deprived of that rounded cycle of contacts and interpersonal reactions with parents and siblings that is so essential to a healthy development through infancy, childhood, adolescence, and youth. In consequence, he was, psychologically, continuously harking back to that childhood period in which he had suffered his arresting deprivations. There he had become compulsively fixated and unable to advance. He thus carried into the age of maturity, and included in his adult personality, the emotional and psychological dynamisms and the relational configurations of his childhood and pre-adolescent periods. His gambling was figuratively the behavior of a child to whom gifts may

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² The New York Academy of Medicine, 2 East 103 St., New York 29, N. Y.

come by mere solicitation, or by teasing for them, as indeed is the case in the child's experience.

In this aetiologic perspective the neurotic gambler can be seen as compulsively acting out a plea to Lady Luck, symbolic of the surrogate figures, mother and father, but mainly mother, for a show of favor, for the affirmative response to the questions: "Do you love me?" "Do you approve of me?" "Do you think I am good, and smart, and strong?"

The neurotic gambler is compulsive in his need to pose these questions and obsessive in his uncertainty. Since he cannot gain a definitive and a for all time reassuring answer, the gambler continues to gamble until he loses. The neurotic gambler seldom, if ever, "quits" when he has made a "killing." He has a compulsion to lose and stays in the game until he loses, in other words until he is without the means to continue gambling. The neurotic gambler's compulsion to lose is understandable, for the more he wins, the more means he has wherewith to gamble, and the more intensive becomes the gambling. Release is to be found only in losing. The questioning can thus be deferred until the next time: until the next game.

Few gamblers come for psychiatric treatment, with gambling as their chief complaint. My patient complained of his sense of depersonalization, not of his gambling. In treatment he reintegrated his personality without much difficulty. After a year of therapy he returned to his accustomed world and its accustomed ways.

Five years later the patient called for an appointment, complaining of what amounted to an acute anxiety. He was again accepted for therapy, and therein we come to *The Gambler and His Love*.

The gambler, as I reported previously, was married and had two children. He was fond of his wife, as a son might be of his mother. He provided her with all the comforts she desired, but did not share life with her, socially or sexually. She concurring, he arranged to have her vacationing or visiting away from home for the greater part of the year, in Florida, and/or the Catskills. The children were placed in boarding schools. He had never wanted

and never thought of legally separating from, or divorcing his wife. He was indeed fond of her—in his own way.

The patient was sexually active, mainly with costly call girls, and casual women. His business required him to travel frequently and widely. His excursions were enlivened with many and bizarre sexual adventures. But these were more in the nature of an exercise than of an orgiastic indulgence. In telling of his sexual ventures he always spoke as if he had been "external to the experience."

But once something extraordinary happened to him—a woman fell in love with him, and she refused to be put off, or to accept the role of a casual partner. The woman was married and the mother of two children. Her devotion to the patient knew no bounds. She pursued him constantly and responded to his every beck and call. She asked nothing of him but his love.

At first he was emotionally unresponsive, aloof, and casual. He relished her sexually but wanted no involvement. In time, however, the woman prevailed, at least to the extent of engaging him emotionally more than any other woman had ever done before. He even suspected that he was beginning to love her. But the more his affections became involved, the more his suspicions grew. Did she really love him? Was it for the love of him that she was sacrificing her husband (who was in fact a shady character with a criminal record), and her two children? Or, was she just a "bum," and after something other than his love. She had "carried on" with him for 18 months, and during that time had not asked him for any money. That puzzled him greatly, and fed his suspicions copiously. He queried her on every score, and though she offered him infinite reassurance and a thousand proofs of her love, he remained unconvinced and suspicious. He was, to quote him, "tortured, nervous, tense."

And this is the way he set about to gain relief! He enlisted the cooperation of his most intimate gambling crony, and with him conspired to put the woman, his love, to a test. The patient was to leave the city for a week, and during this time the friend was to try and "make" the woman. As it was agreed, so was it done! And then came the

Nemesis. The patient returning, his friend reported that though he had tried his very best, employing his every stratagem and resource, he could get nowhere with the woman. She was, he assured the patient, steadfast in her loyalty, and committed in her love.

But, as I am sure you can anticipate, this did anything but reassure the patient. It only enlarged the range of his suspicions, for now he not only doubted the love of the woman but also the fidelity and truthfulness of his friend.

It was all too much for him, and he came back for help. Under the circumstances therapy could only be supportive with a minimum of uncovering and insight. Yet in the end he managed to regain his singular balance. This is the pattern he followed. He gave up his "love," and simultaneously regained his friend.

The unconscious homosexual component in this constellation is, of course, self-evident. But more interesting and significant is what happened with his compulsion to gamble. He had abandoned gambling during the 18 months of his involvement, and resumed it when "the love" was discarded. He now gambled recklessly and lost a good deal of money. His game of preference was gin rummy. Now he played dice and bet on horses. He resumed his sexual contacts with call girls and casuals. He made an abortive attempt to "get closer" with his wife. Nothing came of it. And yet, he found living more tolerable. He

returned to the old and endless pursuit of Lady Luck, who never answers but only smiles the enigmatic smile of the Sphinx.

During therapy he reported an interesting dream. "He was walking somewhere in Chicago. A man and a woman tried to hold him up. They took everything from him. He ran to find the cops. Then ran further and finally gave up."

This slice of life, treated as a psychiatric biopsy, confirms, I believe, this much, that the neurotic gambler always plays to lose, that in his gambling he is obsessively teasing his surrogate figure Lady Luck for a show of favor, yet cannot and will not accept "Yes" for an answer. Such an answer does not square with the deeper facts of his life, nor with the unconscious memories of his irremediable deprivations. And in some ways I am persuaded the gambler is right; for who can make up, and what can cancel out, the egregious loss of the mother's assuring love and the father's supportive sanction. Such a one is doomed to wander through life asking unanswerable questions.

More pointedly, the Gambler and His Love are an unrealistic pair. Only the gambler is real. The gambler has no love. He is incapable of love. Gambling is the gambler's addiction, not his love. For love has the requisite of an antecedent ego maturation—to which the gambler has not attained. He is in these respects severely retarded, a victim of his deprivational experiences.

A CASE REPORT OF GASOLINE SNIFFING

ROBERT V. EDWARDS, M.D.¹

Recently, a 17-year-old boy was encountered who had been sniffing gasoline vapors since age 6.

At age 6, while helping to siphon gasoline from one tractor to another, John discovered inhalation of gasoline vapors was pleasurable. His mother reported he had been observed at least once a month to inhale and exhale gasoline vapors while

pressing his mouth over a gasoline tank. John began smoking cigarettes at age 6. From age 6 to 9, he was anemic and complained of pains in his arms and legs. During that 4-year period, he received "blood medicine" from his physician, who was not informed about the gasoline sniffing. John repeated two grades in grade school. He left school for economic reasons at age 16. From age 14 to 16½, John also drank alcohol excessively. He stated he had been sniffing

¹ Northwestern Mental Health Center, Crookston, Minn.

gasoline 3 or 4 times a year in recent years. He would sniff gasoline every 3 or 4 hours over a 48-hour period: inhalation would last 3 to 5 minutes. John claimed that gasoline sniffing greatly stimulated him and enabled him to think very clearly. He would then feel that he could do anything. On many occasions he sniffed too vigorously and lost consciousness.

John's mother perceived him as possessing a very superior intellect. It was her conviction that her son was destined for greatness. John had the same self-concept. He rationalized that he had not as yet achieved greatness because of adverse events such as the necessity of discontinuing his education. He was an extremely helpful son and would work long hours all day and far into the night attempting to help mother, father, and even the carpenters when they built the barn. John revealed that his father had always worked too hard and never seemed to be interested in his family. He reported: "Mother worries about everything. She always believes some terrible accident is going to happen to members of our family." John believed mother had affected him as he also worried about accidents. His mother had worried about her son's sniffing gasoline whereas the father reportedly regarded the problem as unimportant. John recently changed many of his bad ways because of his fiancée's influence. She made him give up drinking and insisted that he seek psychiatric help for gasoline sniffing. He had been working on a farm where he had been repeatedly observed sniffing gasoline. His employer considered John insane and discharged him. His fiancée refused to consider marriage unless he straightened himself out. For this reason, John consulted a physician about his gasoline sniffing.

During the two hours of interviewing there was no evidence of an organic mental syndrome. The patient's Minnesota Multiphasic Personality Inventory was a 9'05-21 profile which would be typical of people usually classified as hypomanic or manic. The Gorham's Proverbs Test indicated 19 abstract and 2 concrete responses. On the Sentence Completion Test John revealed he was suffering from considerable anxiety. Before hospitalization could be arranged, John

struck a train with his car while traveling around a blind curve. John and his mother were killed.

Dynamically, it appears that John had a lifelong manic hyperactivity designed to achieve greatness as expected by his mother. Because of his powerful need to achieve more than was possible, one might speculate that the patient did experience a subjective increase in efficiency when sniffing gasoline. Clinger and Johnson(1) reported gasoline sniffing in a 16-year-old Negro boy, regarded as schizophrenic, and a 13-year-old white boy who exhibited depression and anxiety. Faucett and Jensen (2) reported a case of gasoline sniffing in an 11-year-old boy. There was no clinical or laboratory evidence in the 3 cases of lead poisoning or liver disease. The 11-year-old boy had an abnormal EEG. All three reported experiencing hallucinations while sniffing gasoline. The 13-year-old boy reported feelings of omnipotence and omniscience while sniffing gasoline. He would then feel that he had unlimited power with the ability to travel great distances and survey the whole world. The 11-year-old boy utilized his hallucinatory experiences while sniffing gasoline to plot the removal of his "bad father". It is of interest that this boy also had smoked a pack of cigarettes daily since age 5 and also lived in an isolated farming community. Pruitt(3) reported a 6-year-old child who was brought to his office inebriated and unable to stand. The mother reported that her child had been addicted to sniffing gasoline for 18 months. No other details were given. The 3 previously reported cases discontinued gasoline sniffing when the underlying emotional conflicts were treated and improved.

SUMMARY

In comparing the 4 cases, it is apparent that gasoline sniffing over a prolonged period need not necessarily produce serious organic damage. Pleasant hallucinations appear to be a reward for sniffing gasoline. In two cases, a feeling of omnipotence and omniscience was clearly reported to be an important effect of gasoline sniffing. Gasoline sniffing may tend to occur in a child with the psychodynamics of a manic.

PROLONGED PHENOTHIAZINE HEPATITIS : REPORT OF A CASE

BRUCE H. BAILEY, CAPT., (M.C.), USA, AND
ROBERT E. KAY, CAPT., (M.C.), USA¹

Since 1955 a number of reports (1-3) have discussed the syndrome of chlorpromazine hepatitis. A gastroenteritis, occurring within 2 to 60 days, usually precedes the development of clinically evident jaundice. The incidence of this complication has varied from 0.5 to 4% and the total dose preceding the onset of this reaction has been as little as 150 mg. Hepatitis has occurred as late as two weeks following discontinuation of the drug. It is not known whether this is an allergic or hepatotoxic manifestation. The majority of cases have evidenced clinical and/or chemical changes indicating intrahepatic obstructive jaundice persisting from one week to 3 months. Cases lasting more than 6 months have been very infrequent. Gebhart, *et al.* (2) mentioned two patients who had abnormalities persisting for 10 months (laboratory findings not reported). The following case, typical of a chlorpromazine hepatitis, emphasizes the persistence of chemical abnormalities despite clinical improvement and reports results of laboratory tests over an 11 month period.

This 23-year-old white, single, male college graduate was hospitalized at another hospital on March 31, 1959, because of paranoid schizophrenia. There was a history of adverse reactions to drugs. Chlorpromazine, 50 mg. q.i.d., was started on the day of admission, increased to 100 mg. q.i.d. on April 2, and continued through April 11, when he was transferred to Walter Reed General Hospital. Trifluoperazine, 10 mg. q.i.d., was begun on that date and continued for 3 days. On April 15, the patient

vomited, was lethargic and anorectic, his urine was dark, and scleral icterus was noted. Liver function studies were done at regular intervals. The most significant variations are noted in Table 1. Additional data revealed normal total proteins, thymol turbidity, cephalin flocculation, blood urea nitrogen, non-protein nitrogen, fasting blood sugar, and prothrombin time. The white blood count on April 16, was 6500 with 36% neutrophils, 48% lymphocytes, 11% eosinophils and 5% monocytes. Repeat white cell counts showed no elevation and normal differential without eosinophilia. Weight loss was prominent in the early months of hospitalization but was enhanced by severe psychotic symptomatology. The patient remained afebrile throughout. Pruritus, of varying degree, heralded initially by a transient, finely papular erythematous rash, occurred intermittently from July through September. His hospital course was characterized by minimal improvement in mental status despite 37 ECT treatments. Other medication given for brief periods during May through August were : probanthine, Benadryl, phenobarbital, Ritalin, meprobamate, amobarbital, atropine, and Anectine. None of these appear to have affected the course of his jaundice. Prochlorperazine (one 30 mg. "span-sule") was given on May 4, 1959.

It is not known whether the use of two phenothiazine derivatives played any part in the prolongation of the patient's hepatic disease. Nevertheless, except for the duration, this case is quite typical of a chlorpromazine-induced intrahepatic obstructive jaundice. Of particular interest is the persistent marked elevation of alkaline phosphatase over the course of 11 months accompanying a steadily diminishing serum bilirubin. It would seem reasonable to suppose that this abnormality may persist for one to two years in this case. Although the absence of necrosis is characteristic, the elevation of the serum glutamic-oxaloacetic

COMMENTS

INTROSPECTION

The Greeks said "Know Thyself." This is a dictum acceptable only with qualification. There is another saying to the effect that the ultimate of knowledge is to know that one knows nothing, despite the fact (begging the question in using the word "fact") that the statement is self-contradictory. However, the word "agnostic" is in a general way useful in more than one practical application.

But to come back to knowledge of self. Commonly two aspects of the person are spoken of—the narrowly physical part, the machine; and the part that has to do mainly with consciousness, and variously referred to as the psyche, mind, entelechy, soul or spirit. This latter, with a bow to Hegel, may be thought of as a sort of upper chamber or attic of the mind. However, it seems reasonable to consider the physical aspect of self before venturing into the arcana of the psychological self as such.

There will probably be general agreement that the common rules of hygiene—cleanliness, temperance in all things, a sense of discipline—should be taught to children and observed by adults. How much farther should self-knowledge and self-ordering of the machine go?

The gastrointestinal canal has been called the *primae viae*, and with good reason; and it may be safe to say that more persons are morbidly concerned with what goes on in this main highway from oral cavity to cloacal orifice than with any other feature of the physical economy. One example of this concern is the so-called *anorexia nervosa*. I remember one patient with this disorder who by fasting had reduced herself to skin and bones and finally could take only water, and in the smallest spaced sips. At this point she became an emergency hospital case. Self-imposed avoidance, for assumed health reasons, of the greatest variety of foods is a common phenomenon. Somewhat less frequent are those persons who worry about one or more of their other organic systems. Occasionally, unhappily, such a fixed con-

cern may be of iatrogenic origin.

The point is that the human body is a marvellous chemical laboratory and a wonderful machine. It is self-regulating, and beyond giving it ordinary decent care, even sometimes without such care, it will run itself quite well without any help from what we laughingly speak of as our ego. In fact when the ego begins to interfere, things are likely to run badly and in the direction of hypochondriasis. These matters are so elementary as hardly to deserve mention, except for the circumstance that it is just such kindergarten rules that the doctor may have to try to teach certain of his patients.

The average person cannot simply by taking thought alter his pulse rate, nor can he regulate the exchange of gases in his lungs or tell the kidneys what to retain and what to eliminate. And as for food, good digestion is more likely to wait on appetite and health on both if the intake is forgotten once it has pleased the palate and passed on its journey downward. In all these matters the body knows how. Leave it alone to do its own work.

If, therefore, it is good advice to the patient worried about his physiology not to try to scrutinize the processes that go on inside his skin, how about the one who is too introspective as to his psychological processes? Here the situation may appear to be somewhat different, but is it essentially? The mental operations of the average person will be molded by the culture of which he is a part. He will develop habits, assume attitudes, form prejudices, acquire beliefs; and all this may be more or less automatic. Indeed, judging by the stereotypes in speech that bulk so large in every-day verbal exchanges, one might say that what we call mental reactions might almost as well be called reflexes. Anything that seriously disturbs this routine flow of events and these automatic responses may predispose to morbid symptoms.

This is where introspection may become unhealthy. Mental tests are valuable within

limits and the patient must of course be encouraged to tell his story. But having told it once it may be a part of his illness to tell it again and again. This pathological introspection may reach the point where the patient appears to have little or no other content of consciousness beside the dreadful state of his own inner self. His "organ recital" tends to become self-perpetuating.

This admittedly, is an extreme situation and difficult to combat, but it illustrates one terminus of the introspective track. It should not take the qualified physician, psychiatrist or other, long to determine how to deal with the factor of introspection in the examination and treatment of each patient; and in listening to his story or his complaints he will try to judge the relative importance of the various matters brought forth and to share his judgment with the patient, if the latter is prepared to receive it. It is common experience that it may be a great relief to the patient to hear the considered judgment of the doctor that some item in his history, over which he has worried and brooded, can be dismissed as negligible, that he can be encouraged to forget it. Forgetting has its place in normal life as well as remembering, and blessed oftentimes is he who is able to forget, and whose trouble can stay forgot.

In psychotherapy this business of introspection is not always given the discriminating attention it requires. It so easily passes over from the salutary "know thyself" of the Greeks to morbid concern about old, unpleasant things perhaps long since consigned to oblivion. For it is in the nature of the depressive mood to dig up unhappy things for vivid recollection and overweighting just as an elevated affect dwells on pleasant memories in keeping with its own euphoria.

It boils down to this: How much introspection is normal, that is, wholesome for the given individual? In how far should the doctor encourage more or less introspection, bearing in mind that for a great many patients self-probing and memory-delving is just about the worst medicine they can take. Indeed morbid introspection is itself a mental disorder. And just as the physical machine works better if one doesn't try to run it consciously, so the psychic machine is likely to run better if not interfered with through morbid self-consciousness.

The ultimate of this kind of self-torture through pathological introspection is vividly set forth in the first part of Dostoevsky's "Notes from Underground"; and the physician practicing psychotherapy might profitably review this story now and then.

"ON WHOSE SHOULDERS . . ."

No group should ever neglect to honor the work of forbears, upon which their own contributions are based. This is particularly true in medicine. Great is the loss to anyone who neglects to study the lives of those whom he follows.

—HOWARD A. KELLY

CORRESPONDENCE

URINARY TESTS FOR PIPERAZINE-LINKED PHENOTHIAZINES AND FOR CHLORPROMAZINE

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: Experience in these laboratories has demonstrated that, although the test for Thorazine and its metabolites in urine, as described by Forrest, Forrest, and Mason (1), is quite satisfactory, the test for the piperazine-linked phenothiazines (2) is not. The latter is complicated by a very high rate of false positive reactions as well as by the relative instability of the reagent.

When the piperazine-linked phenothiazine test was carried out on the urine of 26 of the laboratory and office personnel, 10 false positive reactions were obtained. The following was the distribution of color intensities as determined from the chart: Three, trace; two, 1+; two, 2+; two, 2½+; one, 3½+. When the test was applied to the urine of 19 patients who had not been prescribed a phenothiazine drug for at least 6 months, 12 of the 19 gave positive reactions with the following distribution of intensities: Three, trace; four, 1+; three, 1½+; one, 2+; one, 2½+. Duplicate analyses ruled out the possibility of contaminated glassware. Finally, tests on the morning urines of 4 out of 5 patients receiving placebos of lactose as part of a closely supervised double blind study consistently yielded positive reactions, with few exceptions, over a period of 3 months. The intensities of colors were in the range of trace to 3+ and were still obtained for a period of at least one week after discontinuation of the placebo. The fifth patient gave 10 positive reactions out of a total of 77. A spot check of the patients' capsules, on one occasion, showed that the patients were indeed receiving placebos. The number of these false positive reactions are far in excess of the 2% level reported (2). Heyman, *et al.* (3), using the urine of geriatric patients, have recently reported a rate of

15% false positive reactions with this and two other similar tests. The above results were obtained using urine from young and middle-aged adults.

The false positive reactions were not related to bile in the urine as determined by the Gmelin or Huppert tests for bile pigments, to administration of any one drug, or to sex or race. Neither were they due, as stated above, to the possible excretion of phenothiazine from previous administration, nor to the administration of the wrong capsules in the case of the double blind study.

Regarding the reagent, a good dry preparation of $\text{Hg}(\text{NO}_3)_2$ works best. If it becomes too wet, no reaction is obtained. Since $\text{Hg}(\text{NO}_3)_2$ is extremely hygroscopic, excessive care must be taken in opening and closing the bottle for weighing out of samples. A preparation of the reagent was found to be satisfactory for a period of two months and then was found to decay within a period of a week. The reagent is colorless when first prepared and turns yellow in approximately one hour. This color change, however, does not seem to affect its use.

Contrary to these findings, the test for Thorazine appears to be quite satisfactory. No false positive reactions were noted in 35 tests comprising the urines of 19 of the laboratory personnel and 16 patients. While assaying the daily urines of 8 patients initially receiving 800 mg. of Thorazine per day, it was found that, as the dose was reduced to 600 mg., 400 mg., and 200 mg., at two-week intervals, the color obtained in the test correlated well with the dose administered. All urines were negative 6 to 8 days after discontinuation of the drug. In more than 2000 routine tests, the general impression has been that there is good correlation between color obtained and dose of drug administered. No difficulty was en-

countered regarding the stability of this reagent.

Pollack(4) has also previously confirmed the usefulness and validity of the Thorazine test.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : Referring to the observations of Drs. Posner and Solomon, we are aware of the occurrence of additional "false positives." Since these are caused by both endogenous and exogenous factors, their incidence will vary with the type of hospital population and controls used. Our statistical data for 5 tests for urinary phenothiazine compounds(1) were compiled on the basis of the hospital patients in a neuro-psychiatric Veterans Hospital, the vast majority of whom are in the 20 to 50 year age bracket, with hospital personnel and patients not on phenothiazine medication serving as controls. Further tests conducted by us on different hospital populations (general medical, tubercular, phenylketonuric) have yielded additional "false positives" and these supplementary data have been reported by us(6-8). They refer to the following tests :

1. Rapid urine color test for chlorpromazine (Thorazine), promazine (Sparine) and mepazine (Pacatal)(1).

2. Rapid urine color test for trifluorpromazine (Vesprin)(2).

3. Rapid urine color test for piperazine-linked phenothiazine drugs(3).¹

4. Rapid urine color test for the detection of small amounts of phenothiazine compounds (FPN, General Test)(4).

5. Rapid urine color test for thioridazine (Mellaril)(5). Additional "false positives" observed pertain mainly to tests 2 and 3 which are extremely sensitive and suitable for the demonstration of traces (fractions of a gamma) of phenothiazine compound

per ml. of urine. The high degree of sensitivity is obtained at the expense of a higher rate of "false positives," some of which have been identified as follows :

A. Urines from patients on daily medication of 6 g or more of para-aminosalicylic acid showed "false positives" ranging from the trace to ++ levels in tests 1, 4 and 5, and from the + to +++ levels in tests 2 and 3. See also(3) and(5).

B. Urines obtained from phenylketonuric patients showed "false positives" with tests 2 to 5, ranging from the trace to +++ levels, the latter having been obtained with test 3 in a urine showing 80 to 100 mg. of phenylpyruvic acid according to the phenistix test. See also(5).

C. Urines from persons with impaired liver function—acute or chronic—, with and without showing abnormal urinary bile content, may show "false positives" of intensity trace to + with tests 2, 3 and 4 (2, 3, 4, 5).

D. Urines of patients on therapy with high doses of natural conjugated or synthetic estrogens have shown occasional "false positives" of trace to + levels with tests 2, 3 and 4.

E. Some, in our experience, infrequent but consistent "false positives," not attributable to any factor under A to D were found in control urines of persons without any medication. In the absence of exact knowledge it is assumed that so far unidentified biochemical agents (possibly steroids, ketones, phenolic, indolic or hydroxylated pyridine derivatives) may account for these unexplained "false positives." This hypothesis is advanced on the basis of color reactions obtained *in vitro* with relatively

¹ Test used by Drs. Posner and Solomon.

high concentrations of these compounds.

Regarding the stability of solutions of uranyl nitrate and mercuric nitrate in concentrated hydrochloric acid (test solutions 2 and 3), the pertaining data were mentioned in the original publications, and, in laboratories with controlled humidity, these test solutions remain operative for 6 months and longer, if carefully stored and handled.

It should also be re-emphasized that all evaluation of colors should be performed strictly as specified, i.e. within 20 seconds for test 4, and, within 30 seconds for tests 2 and 3. All subsequently appearing color or unspecific darkening of urines should be disregarded.

We are unable to offer any other helpful comment with regard to the high incidence of "false positives" in the test series on 51 individuals conducted by Drs. Posner and Solomon. In our own extended series of controlled tests, excluding phenylketonurics and patients on para-aminosalicylic acid, we found our "false positives" to approximate 5% for test No. 2, 3, 4 which is well below the figure of Heyman's(9) series (done on geriatric patients) and far below Posner's.

In spite of the occurrence of "false positives," the tests constitute valuable diagnostic tools, in clinical psychiatry if properly evaluated and interpreted in the light of the above, especially since we have not seen any "false negative" tests in any of the

5 different procedures mentioned above. In this connection it should be kept in mind that extreme urine dilutions after excessive fluid intake may give rise to very inadequate color reactions.

In all cases of apparent "false negatives" the tests should be repeated on another urine specimen, to be obtained 1 to 3 hours after carefully supervised administration of drugs, preferably in form of liquid concentrates.

FRANKL'S LOGOTHERAPY

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : In your August issue Hans A. Illing, Ph.D., reviewed Victor E. Frankl's book : *Das Menschenbild der Seelenheilkunde*. This review is not critical but slighting. Frankl in his book does not "deal with a multitude of topics," he discusses one topic, namely the image of man in different kinds of psychotherapy.

Frankl pays due respect to the genius of Freud but he does not treat psychoanalysis as a dogmatic religion and he agrees with Ludwig Zeise whom he quotes : "... the concept of depth (in psychoanalysis) is one-sided and incomplete."

It seems to me unfair to Frankl and to the readers of your *Journal* when the reviewer distorts the sense of the author's writing by taking a few words out of the context and quoting them. Frankl does not say that "the mass neuroses of mankind cannot be resolved." He says that the pathology of the spirit of the age, the collective neurosis of mankind, cannot be overcome "without an appeal to (man's) freedom and responsibility." These are basic concepts in Frankl's Logotherapy which the reviewer has completely overlooked.

G. Kaczanowski, M.D.,
Ontario Hospital,
Whitby, Ont.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : In reply to the foregoing, Dr. Kaczanowski probably raises the important question, whether a report on any book should be critical and deal extensively with the content or should, if this is not possible for reasons of space, not be dealt with at all.

My reports ("New German Psychiatria and Psychologica," the third installment of which appeared in the August issue of the *A.P.A. Journal*) are notices of German books, and not reviews in the customary sense. They are rarely critical and hardly ever "slighting," as Dr. Kaczanowski interprets my report to be ; a book, which in my opinion has little value, will not be selected for a report in the first place.

I have had much personal correspondence with Dr. Victor E. Frankl, and admire him greatly ; hence my inclusion of his book in my reports. I maintain that, while "logotherapy" is his primary brain-child, there is, and should be, a "multitude of topics" in his book. When I quote Frankl (in a report consisting of but two sentences!) as being not in agreement in Freud's *Lehre*, Dr. Kaczanowski in *his* way says the same. My translation of a passage in Dr. Frankl's book seems to me *substantially* similar to that of your reader. Above and beyond this, translators are known to differ in their translations. Lastly, the opinion of the reviewer or "reporter" is his own, to which he is entitled.

Hans A. Illing, Ph.D.,
Los Angeles, Calif.

A CASE FOR JEFFERSON¹

Harrison loves his country too,
But wants it all made over new,
He's Freudian Viennese by night,
By day he's Marxian Muscovite.
It isn't because he's Russian Jew.
He's Puritan Yankee through and through.
He dotes on Saturday pork and beans—
But his mind is hardly out of his teens—
With him the love of country means
Blowing it all to smithereens
And having it all made over new.

NEWS AND NOTES

THE ISRAEL S. WECHSLER LECTURE.—Dr. Macdonald Critchley, F.R.C.P., Senior Physician of the National Hospital for Nervous Diseases, Queen Square, London, and Neurologist for Kings College Hospital, London, England, will deliver the Sixth Annual Israel S. Wechsler Lecture on December 9, 1960 at 8:30 p.m. in the Blumenthal Auditorium of the Mount Sinai Hospital, New York City. Dr. Critchley's lecture is entitled: "The Nature of Animal Communication and its Relation to Language in Man."

THE HOFHEIMER PRIZE.—This prize of \$1,500 is awarded annually by The American Psychiatric Association for an outstanding research contribution in the field of psychiatry or mental health which has been published within a 3-year period up to the date of the award. Studies in press or in preparation are not eligible for this award.

This competition is open to citizens of the United States and Canada who were not over 40 years of age at the time the study was submitted for publication; or to a research group whose median age does not exceed 40 years. The next award will be made at the annual meeting of the Association in May 1961. Entries submitted to the Prize Board before March 1, 1961, will be considered. It is imperative that 8 reprints or duplicated copies of each entry as well as the necessary data concerning age and citizenship be sent to David A. Hamburg, M.D., Chairman, Hofheimer Prize Board, National Institute of Mental Health, Bethesda 14, Md. All entries are independently evaluated by each member of the Hofheimer Prize Committee and final selection determined by equal vote.

UNIVERSITY OF CALIFORNIA SYMPOSIUM ON "CONTROL OF THE MIND."—This symposium will be held Jan. 28 to 30, 1961 in San Francisco. The topic will be discussed from many viewpoints: "the physiological and biochemical, the psychologic, sociologic and historical, and from the point of view of religion, mass communication, and

political philosophy." A considerable number of well known writers and scientists will participate.

The office of Public Information of the University announces this as "an unprecedented symposium"; it unquestionably will be. For further information write to the Department of Continuing Education in Medicine, University of California Medical Center, San Francisco 22, California.

RESEARCH TRAINING IN PSYCHIATRY.—The Graduate Educational Program of the State University of New York Downstate Medical Centre offers a 2-year program of research training in psychiatry leading to the degree of Doctor of Medical Science. The course is open to M.D.'s who have completed 3 years of residency training in psychiatry. Candidates will also be accepted after 2 years of residency, in which case, the final year of residency will be taken at the psychiatric division of Kings County Hospital, concurrently with this program, making a total of 3 years for the combined program. It provides an opportunity to do research and offers courses in research methods in psychiatry. A broad interdisciplinary faculty conducts the teaching and supervises research of candidates.

Each candidate accepted will be granted a fellowship of \$7,500 for the first post-residency year and \$8,000 for the second year. Three-year candidates will, in addition, receive \$7,100 for the final residency year.

Applications for the academic year beginning September 1961 should be submitted before February 1, 1961. For information write to: Office of Admissions, Downstate Medical Centre, 450 Clarkson Ave., Brooklyn 3, New York.

THE JOINT MEETING OF THE JAPANESE ASSOCIATION OF CORRECTIONAL MEDICINE AND THE MEDICAL CORRECTIONAL ASSOCIATION OF AMERICA.—This meeting was held in Tokyo on September 20 and 21, 1960 on The Problem of Stress in Correctional Institutions.

About 20 American delegates were present, and prior to the meeting they were conducted through various correctional institutions in Tokyo and vicinity. Among these were: the Tokyo Juvenile Detention and Classification Home, the Fuku Prison, the Tokyo Women's Guidance Home and the Hachiojo Medical Prison.

In the course of the exceptionally fine program many research papers were read to an audience of 450 to 500, consisting mainly of psychiatrists and other medical specialists, psychologists, social workers, members of the staff of the Ministry of Justice and other correctional personnel of professional standing.

American speakers included Dr. Winfred Overholser, Superintendent of St. Elizabeths Hospital, Washington, D. C. on "The Role of Psychiatry in Correctional Administration," Dr. James V. Bennett, Director of the Bureau of Prisons, U. S. Department of Justice, on "Psychiatric Problems in Prisons," Dr. Harry R. Lipton, Atlanta, Ga., on "Stress in Correctional Institutions," Dr. Sarah Geiger, Director of the Milwaukee Child Guidance Clinic on "Electroencephalographic Changes in Aggressive Behavior," and Dr. Ralph S. Banay, Secretary of the Medical Correctional Association of America on "Violent Youth."

Japanese speakers included: Tetsizo Kosimo, Minister of Justice; Dr. Nagahide Ishibashi, President of the Japan Medical Association; Dr. Masao Otsu, President of the Japanese Association of Correctional Medicine; Dr. Akira Masaki, President, The Japanese Correctional Association; Dr. Tsuneo Muramatsu, Dean, School of Medicine, Nagoya National University; Prof. Sadao Hirose; Prof. Kokichi Higuchi; Dr. Toru Matsumoto; Dr. Akira Kobayashi; Dr. R. Yamanaka; Dr. Tamio Sase; Dr. Takayuki Tsuboi; Messrs. Yoshitsugu Baba, Vice-Minister of Justice; En. Ohta, Vice Governor of Tokyo; Taka Hashi; Shigeru Nishi; Yoshiyuki Tanaka; Noriyuki Hanakawa; Ryuichi Hirano; Tory Matsumoto; Teizo Ichikawa; Bunsaku Nakao; Ichiro Ohsawa and Mrs. Tsuneko Mita, Director of Tokyo Women's Guidance Home.

An outgrowth of the Meeting was the founding of the International Association of Correctional Medicine. The officers elected

were Winfred Overholser, M.D., president; Masao Otsu, M.D., vice-president; and Ralph S. Banay, M.D., secretary. It is planned that the new association will meet bi-annually in different countries.

The American delegates were given a warm and cordial welcome and were generously entertained by their hosts. A special concert was given for the group in the Music Room of the Imperial Palace, and they attended a performance at the Kabuki Theater, where they were introduced to the actors. They were escorted through the Summer Villa of the Emperor and visited many fine shrines, temples and historical buildings. One of the most interesting of these was Shosoin in Nara, situated in a garden closed to the general public, where priceless Imperial treasures are housed. Once a year the Emperor, who is said to possess the only key, opens the house to inspect these treasures. Another highlight was the visit to the Sacred Stables of the Toshugo Shrine in Nikko to see the originals of the famous three monkeys "Hear no Evil," "Speak no Evil" and "See no Evil." Another famous sculpture there is a cat which seems to be sleeping but which, according to the legend, is protectively watching over the inner sanctum.

This fine opportunity for scientific and social exchange between two similar groups and the kind of hospitality extended to the American delegates are a symbol of the increasing friendship between the two countries.

THE AMERICAN ASSOCIATION FOR THE STUDY OF HEADACHE.—This association was organized this Summer at the time of the Annual A.M.A. meeting in Miami. The following officers were elected: President, Henry D. Ogden, New Orleans, La.; Vice-President, Walter C. Alvarez, Chicago, Ill.; Treasurer, Robert E. Ryan, St. Louis, Mo.; Secretary, Bayard T. Horton, Rochester, Minn.; Moderator, George T. Waldbott, Detroit, Mich.

The Association welcomes to its membership any physician who is interested in the study of headache. Further information can be obtained from the Secretary at the Mayo Clinic, Rochester, Minn.

GUEST LECTURE SERIES IN PHILADELPHIA.

—Dr. Philip Mechanick, Acting Medical Director of Philadelphia Psychiatric Hospital, announces the second annual series of guest lectures for residents: Maurice E. Linden, M.D., Geriatric Psychiatry; Charles Brenner, M.D., Denial; Kenneth E. Appel, M.D., Psychotherapy; John Donadeo, M.D., Symbolism; Jacob A. Arlow, M.D., Ego; Kenneth T. Calder, M.D., Affects as Signals; Bertram D. Lewin, M.D., Dreams; Bernard Bandler, M.D., and Dexter M. Bullard, M.D., topics to be announced.

The program is under the direction of Dr. Morris W. Brody, Director of Resident Training.

FIRST INTERNATIONAL CONGRESS OF ENDOCRINOLOGY.

—The proceedings of this congress held in Copenhagen in July 1960 have been published in 2 supplements to *Acta Endocrinologica* accompanying volumes 34 and 35.

The first supplement contains abstracts of the symposium lectures and round table discussions with translations into interlingua and edited by Christian Hamburger. This supplement runs to 426 pages.

The second supplement contains abstracts of short communications and is edited by Fritz Fuchs. This supplement, exclusive of indices, runs to 1,358 pages.

These volumes are published by Periodica in Copenhagen, 1960.

FRENCH GOVERNMENT.—M. Raymond Triboulet, French Minister of Veteran's Affairs and member of the Cabinet of France on a goodwill visit to the United States tendered a reception for the Veterans Committee of the People to People program at the French Consulate in New York City, October 22, 1960. M. Triboulet presented to Dr. Winston E. Burdine, prominent Atlanta psychiatrist and past National Commander of the AMVETS, the Croix De Merite, Combatant Military Medal for his outstanding work on the People to People program. This decoration is one of the highest and most coveted of the government of France and is an expression of their goodwill and appreciation of Dr. Burdine's dedicated efforts on behalf of the Worlds Veterans Federation and his creation of better

understanding between the different peoples of the world during his visits to the U.S.S.R., France, and the major countries of the world.

INTRODUCTION TO ANALYTICAL PSYCHOLOGY.—University of California Extension announces its second residential workshop on "Introduction to Analytical Psychology for Clinicians."

The Conference will be held June 3-15, 1961, at the Asilomar Conference Grounds, Pacific Grove, California, 6 miles from Carmel and 125 miles from San Francisco.

The prerequisite is a Ph.D. or M.D. degree or equivalent in professional experience, and consent of staff, consisting of Bruno Klopfer, Ph.D., (Coordinator); Rivkan Kluger, Ph.D.; Joseph Henderson, M.D.; and Marvin Spiegelman, Ph.D.

The enrollment fee is \$95.00. A limited number of \$50.00 tuition scholarships will be available. Information concerning veterans benefits will be supplied on request. For further information write to Department of Social Sciences, University Extension, University of California, Los Angeles 24. The deadline for receiving applications is May 1, 1961.

INTERNATIONAL PSYCHOSOMATIC SEMINARS.

—A 3-months world cruise by the American President Lines visiting 20 or more foreign ports and leaving New York in October or November 1962 is planned, providing a sufficient number of qualified persons volunteer their services. The understanding will be to conduct teaching seminars in every port visited. Countries included will be Japan, Okinawa, Taiwan, China, Vietnam, Malaya, Ceylon, India, Pakistan, Egypt, Italy, Spain, France.

Reservations will have to be made well in advance and those interested should communicate with James W. McCartney, M.D., 223 Stewart Ave., Garden City, N. Y.

IN HONOUR OF DR. STANLEY COBB.

On October 14 and 15, 1960 the Massachusetts General Hospital arranged a programme which served the double purpose of dedicating the Stanley Cobb Laboratories for Research in Psychiatry, and the ob-

servance of the 25th anniversary of the Psychiatric Service of the hospital.

After a scientific session during the forenoon of the 14th the Dedicatory Programme began with a luncheon at the Massachusetts General Hospital at which Mr. Phillips Ketcham, President of the Corporation, Massachusetts General Hospital presided and the speaker was Seymour S. Kety, M.D., Research Director, National Institute of Mental Health and Member, Scientific Advisory Committee, Massachusetts General Hospital. The luncheon programme was followed by a tour of the Psychiatric Research Laboratories in the Warren Building, M.G.H.

The Anniversary dinner was held the same evening at the Harvard Club in Boston.

THE WORLD MEDICAL ASSOCIATION ELECTS OFFICERS.—At its 14th General Assembly held in West Berlin, Germany, September 15-22, 1960, The W.M.A. elected the following officers:

President (1960-61): Dr. Paul Eckel—Germany; President Elect (1960-61): Dr. Antonia Moniz Aragão—Brazil.

Members of Council (1960-63): Dr. J. G. Hunter—Australia, Dr. L. W. Larson—U.S.A., Dr. Antonio Spinelli—Italy, Dr. Hector Rodriguez H.—Chile.

Secretary General (1961): Dr. Heinz Lord.

The Council elected the following officers (1960-61): Chairman of Council, Dr. Gunnar Gundersen—U.S.A.; Vice Chairman of Council, Dr. Felix Worré—Luxembourg.

Executive Editor—*World Medical Journal*, Dr. Stanley S. B. Gilder—U.K.; Associated Editor, Dr. J. R. Gosset—France.

FOURTH LATIN AMERICAN CONGRESS OF MENTAL HEALTH.—This Latin American Congress will be held December 4-10, 1960 in Santiago, Chile.

The central theme of the Congress will be community organization and the programme will comprise several general headings including Mental Hygiene in relation to Public Health, to Education, to Social Disorganization, to Successive Life Periods.

Professor Agustin Tellez is President of

the Organization Committee; Professor Carlos Nassar G. is Secretary General.

Information may be obtained from Mottram P. Torre, M.D., Project Director, 162 E. 78th St., New York 21, N. Y.

NATIONAL TRAINING CENTRE FOR REMOTIVATION.—On October 4 at the APA designated the Philadelphia State Hospital as the National Training Centre for Remotivation. Dr. Robert S. Garber, chairman of the APA's Committee on Remotivation and Dr. John E. Davis, Commissioner of Mental Health for Pennsylvania, commended the work done in Remotivation at the Philadelphia State Hospital and the suitability of this designation.

Dr. Garber pointed out that the Remotivation programme, which is supported by the Smith Kline and French Foundation, has, by being introduced to some 600 nurses and aides in 35 hospitals by the Philadelphia training teams, been carried to approximately 2,200 other psychiatric personnel in about 100 additional hospitals. Dr. Garber particularly cited the work of Dr. Eugene L. Sielke, Superintendent of the Philadelphia State Hospital, and Miss Helen Edgar, director of nurses, for their leadership in the programme.

Other regional training centres have been established at the Central State Hospital, Norman, Okla.; Western State Hospital, Staunton, Va.; and the Essex County Overbrook Hospital, Cedar Grove, N. J.

INTERNATIONAL CONGRESS FOR INDIVIDUAL PSYCHOLOGY.—The Eighth International Congress for Individual Psychology was held at the Neuro-Psychiatric University Clinic of Vienna from August 28 to September 1, 1960. The main subject considered was: "Social Interest." Professor Dr. Hans Hoff, Honorary Chairman of the Congress, gave the opening address, in which he outlined the influence that Individual Psychology has had upon developments in the field of neuro-psychiatry.

More than 200 participants were registered. The following officers were elected:

President, Alexandra Adler, M.D., New York; Vice Presidents: Rudolf Dreikurs,

M.D., Chicago; Professor Oscar Spiel, Vienna; Dr. Victor Louis, Zurich, was re-elected General Secretary. The next International Congress will take place in 1963.

DR. NORMAN SLOAN.—Dr. Sloan died on October 6, 1960 at Doctors Hospital in New York City at the age of 43. He was born in Winnipeg, Canada, and was graduated from the University of Manitoba in 1942. He received a Master of Science Degree in Neurology from McGill University in 1949. Postgraduate training was at the Montreal Neurological Institute and the Columbia Psychoanalytic Clinic in New York. He was a staff psychiatrist and consulting neurologist at the Orangeburg State Hospital in New York from 1949-51, and a Research Fellow at the New York Psychiatric Institute from 1949-54.

In World War II he was a Captain in the Royal Canadian Army Medical Corps. In the past decade he had been active in neurophysiological research and had authored numerous articles in this field.

THE PROCESS OF SCIENCE.—In primitive societies explanation of natural phenomena—including human behaviour—was usually based on an assumption of supernatural forces. The assignment of supernatural causes for natural phenomena stemmed from the imagination of man based on his observations of nature. These pre-scientific ideas are not greatly different from the hypotheses which constitute the first step in scientific research. The difference between science and other processes of intellectual invention is that to scientists an idea is not regarded as a fact or as a truth

until it has met rigorous tests of validity.

The scientist calls a raw idea a hypothesis. After the idea has gathered sound supporting evidence it becomes known as a theory. Only after some kind of direct proof has been demonstrated, is the precious label of "fact" bestowed, and even that is tentative. Scientists must always be willing to strip away the credentials of a "fact" if new, conflicting evidence appears.

Science highlights what is true in large part by revealing what is not true, *i.e.*, what has failed the validity checks. The experimental methods of science free man from the confusing maze of conflicting opinion. It is as though the compasses by which man steered his various courses pointed helter-skelter in every way and science provided ways to test compasses.

ORT E. Reynolds, Director,
Office of Science,
Dept. of Defense.

FOUNDER PORTRAIT FOR CENTRAL OFFICE A.P.A.—Dr. Philip C. Rond, Associate Professor of Psychiatry, Ohio State University, Columbus, Ohio presented to the Central Office of the American Psychiatric Association on October 10, 1960, an oil portrait of Dr. William Maclay Awl, one of the 13 Founders of the Association of Superintendents of American Institutions for the Insane, and former superintendent of the State Hospital at Columbus.

This donation is gratefully received and it is hoped that arrangements may be made to place the portrait of Dr. Awl on view at the annual meeting of the A.P.A. in Chicago in May 1961.

DEFINITION

I think it might be well to substitute the term psychological medicine for psychiatry, in order to disidentify this branch of medical practice from the flotsam and jetsam on the psychiatric sea.

—C. CHARLES BURLINGAME

BOOK REVIEWS

AN INTRODUCTION TO CHILD PSYCHIATRY. By Stella Chess. (New York : Grune and Stratton, 1959, pp. 254. \$5.25.)

This brief but comprehensive survey of child psychiatry was written for newcomers to the field and for individuals who need a ready reference to the psychological problems of children. Using a simple and direct approach, the author outlines methods of evaluating children and their parents, enumerates the specific dynamics of various psychological problems, and reviews the current treatment of these problems.

A sizeable portion of this book is devoted to history-taking and to the problems of diagnosis. Many helpful specific recommendations are presented in this section which will help even the inexperienced therapist to get a more accurate, comprehensive picture of the whole problem of the child with emotional difficulties.

The discussion of the various categories of emotional problems is, perhaps, one of the book's greatest contributions. Avoiding lofty speculations, the author presents understandable formulations of the dynamics of many emotional disorders in a clear, logical fashion. This section is invaluable for individuals who have not had the clinical experience to provide them with working knowledge of the dynamics found in children with problems.

The last section of the book deals with the treatment of children with various problems. No one method of therapy is advocated, but the author objectively reviews the available methods of treatment of a wide range of problems, including organic brain damage, neurosis, and childhood schizophrenia. The issues connected with mental retardation are given adequate consideration.

The author has included a carefully selected bibliography at the end of each chapter. There is a helpful index of subjects.

This book is highly recommended as being just what the title says it is. Not only psychiatrists and pediatricians, but students in the related disciplines will find it very profitable.

RICHARD J. BEALKA, M.D.,
Minneapolis, Minn.

THE BIOCHEMISTRY OF DEVELOPMENT. By Jean Brachet. (New York : Pergamon Press, 1960, pp. 320. \$10.00.)

There has been no text on the biochemistry of development for some 10 years. Professor

Brachet's volume is therefore to be welcomed on this, as well as upon other grounds, as a most useful summary of the advances which have been made in this field during the last decade—a decade which has witnessed heroic progress in the biochemistry of development. The author's treatment is detailed, and he deals with gametogenesis, spermatogenesis, fertilization, cleavage, invertebrate and vertebrate eggs, biochemical interactions between the nucleus and the cytoplasm during morphogenesis, and with the biochemistry of differentiation. There are full chapter bibliographies, and excellent author and subject indexes.

To anyone interested in any way living things increase in complexity, this is an indispensable volume.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

RECENT ADVANCES IN NEURO-PHYSIOLOGICAL RESEARCH. Edited by D. Ewen Cameron and Milton Greenblatt. (Washington : American Psychiatric Association, 1959, pp. 136. \$2.00.)

This paper-bound volume is Number 11 in the APA series of *Psychiatric Research Projects*. It contains the scientific papers and discussions of a Regional Research Conference held November 8-9, 1957, in Montreal under the joint auspices of the Department of Psychiatry, and the American Psychiatric Association's Committee on Research 1957-58. The titles and authors are : "Patterns of Intra-Familial Communication" by Nathan B. Epstein, M.D. and William A. Westley, Ph.D. ; "Issues in a Therapeutic Organization" by Milton Greenblatt, M.D., and Daniel J. Levinson, Ph.D. ; "Types of Memory Dysfunction in Senescence" by V. A. Kral, M.D. ; "The Memory Defect in Bilateral Hippocampal Lesions" by Brenda Milner, Ph.D. ; "Sleep Threshold Techniques" by C. Shagass, M.D., and A.B. Kerenyi, M.D. ; "The Use of the Electrogastrograph in Problem Identification in Psychoneurotic Patients" by H. S. Morton, M.D., J. F. Davis, M. Eng., M.D., and Z. J. Lipowski, M.D. ; "Activation : A Neuropsychological Dimension" by Robert B. Malmo, Ph.D. ; "Neurolathyrism in the Rhesus Monkey Induced by B, B' Iminodipropionitrile" by Edward M. Gore, Frazer V. Hadley, Richard Tislow, M.D., and Joseph Seifter, M.D. ; "A Biological Basis for Psychopathology" by Howard Liddell, Ph.D.

A.G.

THE RELUCTANT SURGEON. A BIOGRAPHY OF JOHN HUNTER. By *John Kobler*. (Garden City, N. Y.: Doubleday & Co., 1960, pp. 359. \$4.95.)

If the meaning of John Hunter to science—particularly medical science—and therefore to humanity has been too little appreciated outside the professional community, this book should serve to repair the flaw in the information of otherwise literate persons.

The author recalls some of the titles that have been bestowed by scientists and scholars upon this 18th century Scot (1728-1793), and in his book he tells the reasons. John Hunter has been variously called "the most important naturalist between Aristotle and Darwin," "a philosopher whose mental grasp embraces the whole range of nature's works," "with the exception of Hippocrates, the grandest figure in his profession," "a urologist a hundred and fifty years ahead of his time," "the first to teach the science of surgery as Paré two hundred years before had advanced the art," "the Shakespeare of medicine," "one of the greatest men the English nation has produced." Kobler also remarks that the *Encyclopedia Britannica* "devotes more space to Hunter than to Linnaeus, Paré, Harvey, Jenner, Lister, Simpson, Pasteur, Freud, or Fleming."

The brothers William and John Hunter were about as unlike as any two men could be. William was well-behaved, ambitious, snobbish, perhaps a trifle "unco 'guid." John was runty, red-haired, wayward, the youngest of 10. William was university trained and destined for the Church, but considered himself unfit "to wag my pow in a pu'pit" and soon became medical apprentice to William Cullen. At 21 he was in London, a favorite pupil of Smellie, the famous man-midwife, as accouchers were disrespectfully called, and on his way in a brilliant career as surgeon, obstetrician, anatomist, with many students taking his lectures and demonstrations. John, intensely curious about everything growing, animals and plants, was unmanageable in school, was taken out at 13 and had no further formal education. At 20, and still apparently without prospects, he was taken on by his brother William in London as an assistant.

Here he was promptly engrossed in the mysteries of the human body, and became expert in anatomising—also in securing the necessary material. He never engaged in Burkeing but he knew the ways of the resurrection men and quite probably indeed shared them.

During 12 years together "the brothers kept up a rate of activity that defied the limitations of time and human energy, working sometimes

in collaboration, sometimes independently, they undertook 17 major investigations and innumerable minor ones, invented surgical procedures, taught ever-increasing numbers of students, pursued their own professional education, and treated patients."

John's semi-literacy was his main handicap. "Few scientists have ever been so poorly equipped with the tools of communication." But his dissections and demonstrations were eloquent. "I turn over the volume of nature," said John Hunter, and his penetration into that volume went beyond that of his contemporaries. He anticipated Darwin "by almost 100 years in enunciating the principle that the human embryo at each stage of development resembles the mature form of some lower species."

Both brothers were tireless collectors, but John went far beyond William; the building of his museum of comparative anatomy and natural history became a real addiction, running him heavily into debt. "It was the most important of its kind before or since." The Hunterian Museum is now the property of the Royal College of Surgeons. The Government had purchased it for £15,000, "about a fifth of what John spent on it."

The first private anatomical school in America was established by William Shippen of Philadelphia on his return in 1762 from several years study with the Hunters.

Contrasting with John, William had social as well as professional aspirations. His practice had become largely obstetrical. He made man-midwifery not merely respectable, but fashionable. He was sought after among the nobility and at Court; he delivered 10 of Queen Charlotte's 15 children.

John had seen service in the Seven Years' War while William thrived at home. He had replaced his brother by a new assistant and an estrangement began. John had hard grubbing, with his army pension of 5 shillings a week. Gradually, he reestablished himself as surgeon, investigator, innovator and collector, and in due course—again in contradistinction to William—considered the problem of marriage.

Never was a stranger love affair than that of John Hunter and Anne Home. Discussing their marriage plans, it was John who put off the date and gave the wrong reason. It wasn't his low economic status, but an experiment on himself he wanted to try—to find out, if he could, whether syphilis and gonorrhoea were simply, as he thought, different manifestations of one disease. He infected himself from one of his venereal patients, obviously suffering

from gonorrhoea. He watched for symptoms of syphilis in himself and was not disappointed. His patient harbored both organisms. He allowed the disease to run its course for three years before "curing" it, as he believed, with mercury. Four years after the initial postponement, John and Anne were happily married. Of four children of the first five years of marriage, two died in infancy, and two reached adult life, both sooner or later becoming mental cases.

Throughout his professional career, John was enviably associated with St. George's Hospital where students flocked to him from other doctors who walked the wards. As a lecturer, however, he was hopeless at first and never a success. On one occasion when he found an audience of one, "he dragged a skeleton into the room, seated it, and with a pawky grin began: 'Gentlemen . . .'"

Early American medicine owed much to William and John Hunter, especially to the latter. "Nearly the whole of Colonial physic, surgery, and obstetrics, as they began to move away from empiricism reflected Hunterian doctrines." It was William Shippen who led the parade of Colonial pioneers to the famous brothers in London. The debt was formally acknowledged when Benjamin Franklin, president of the American Philosophical Society, proposed the election of John Hunter as an honorary member of that distinguished brotherhood; and it was done.

At home there were envious enemies. John was so far in advance of most of his contemporaries in his physiological and anatomical researches, in his prodigious industry and in his startling and successful innovations in surgery—while adhering to his rule never to perform an operation that in like circumstances he would not have done upon himself—that jealousy and hostility in lesser men were to be expected. He was not boasting when he said: "I am a pigmy in knowledge, yet I feel as a giant compared to these men."

Kobler's book is a vivid story of the dramatic life of John Hunter. But it is much more; it carries through the parallel lives of the two brothers, and it reflects the social climate of the two countries so intimately involved, with their mutual prejudices. Numerous well known figures whose paths crossed those of the Hunters also have their exits and entrances and personalities, and events fit into their places as related to that extraordinary individual who was John Hunter. And again he could say without boasting: ". . . when I am gone there will not soon be another John Hunter." This

book, excellent as it is, has no photograph of the hero.

In the coat-of-arms of the family was the motto: "Hunter blow your horn." In their several ways both William and John did.

C. B. F.

THE OFFICE ASSISTANT IN MEDICAL PRACTICE.

By *Portia M. Frederick and Carol Towner.*

(Philadelphia: W. B. Saunders Company 1960, pp. 407, \$5.25.)

Essentially a teaching aid for schools where there are training programs for medical assistants, it will also serve as a reference manual for those working in doctors' offices and learning their duties on the job. Likewise, it will help busy doctors in training their office assistants, outlining as it does not only office procedures but also basic medical techniques and knowledge such as how to give injections, prepare medications and assist in physical examinations.

P. P. T.

REHABILITATION OF THE MENTALLY ILL—

SOCIAL AND ECONOMIC ASPECTS. Edited by *Milton Greenblatt, M.D. and Benjamin Simon, M.D.* (Washington, D. C.: American Association for the Advancement of Science, 1959. pp. 260. \$5.00.)

The volume brings together papers presented December 29 and 30, 1957, at a symposium in Indianapolis, sponsored by the American Psychiatric Association, the Section on Social and Economic Sciences of the American Association for the Advancement of Science and the American Sociological Society. The book is a readable, concise presentation of current thinking and ideas of a group of men closely associated with developments in the field.

The content area of rehabilitation of the mentally ill is reported in Part I, by Ewalt, Greenblatt, Hunt and Simon. Greenblatt and Simon state that the maximum rehabilitation effort in the hospital may be evoked through greater understanding of the institution's social organization. Mental illness reflects the harsh conditions imposed by society upon its citizens. Basically, the conditions are treatable and preventable through social change. The hospital as a social organization may aid or retard recovery. Interpersonal relationships and therapeutic use of self are underscored as important factors to this end. Charlotte Green Schwartz, in discussing this section says that effective help to the mental hospital patient requires the development of community pro-

grams. However, treatment and rehabilitation, no matter how modern the mental hospital may become, will be incomplete if the process of helping patients return to a place outside the hospital is confined to intramural preparation alone.

The philosophy of rehabilitation is discussed by Martin in Part II, and program development by Notman. The discovery and analysis of the patient's assets (in contrast to "treatment," which is a direct attack on the disability), is the aim of the rehabilitation process. Notman notes there are three teams within a mental hospital on which the psychiatrist may serve—the custodial, the therapeutic and the rehabilitative. The psychiatrist joins one or the other of these teams and his presence on it gives it dominance. The one selected becomes the one with the most status in the hospital. The training of the psychiatrist leads him often to choose the therapeutic team. His lack of understanding and interest in the areas outside of his own direct therapy, often hampers the rehabilitation of patients. Work programs are discussed by Landy and Raulet, ancillary therapies by Key, and Wittkower and Azima advance a hypothesis for occupational therapy formulated in dynamic terms. The potential of work and tangible rewards serve as motivating factors. The value of realistic work is highlighted. John Cummings in his discussion indicates that rehabilitation helps overcome handicaps. In psychiatric disorders those handicaps may be orientation disturbances, communication disturbances or the loss of group skills.

Part III covers the transition from hospital to community. Greenblatt briefly presents rehabilitation goals. The section on vocational rehabilitation by Temple Burling is a discussion of Sivadon's transitional home in Paris for male patients who live together while adjusting to employment. Vocational rehabilitation techniques or current research projects in the vocational area are not presented.

Brooks ably describes a Half Way House with helpful details for day to day problems that arise. Knudson makes brief mention of industrial therapy and the V.A. program within the Veterans Administration for employing patients while still in the hospital as an aspect of their preparation for a job in the community. Carmichael presents his work in after care with a brief discussion of the Fountain House Social Center Program. Hewett, in discussing this section, indicates that the transitional programs are aimed at reducing the disability induced by prolonged hospitalization.

The implications of rehabilitation are presented by Gruenberg and Huxley who suggest

methods for organizing staff interaction and inter-agency communication.

Kris studied 250 psychotic patients in an after care clinic of whom 189 were schizophrenics and showed that one-third of untreated patients suffer relapses and must return to the hospital. When patients were maintained on drug therapy, only 10% return.

Black describes the Altro sheltered workshop program as a resource for rehabilitation and Olshansky, presented a study on employer receptivity to hiring former mental patients. Three-fourths of 200 interview employers expressed a willingness to have ex-patients work for them, but only 27 had knowingly employed an ex-mental patient. Olshansky suggests that instead of educating employers it might be more profitable to concentrate effort on the better preparation of the patient for release. Knight Aldrich suggested that all rehabilitation programs be carefully studied for leads as to areas that might prove profitable for research and might offer reasonable rewards from expended money.

The book is a valuable document, outlining the progress in the field of psychiatric rehabilitation and some of the problems and issues that are its major concern. It is recommended reading for psychiatrists in mental hospitals and for those who work with adults in community psychiatric facilities. It will be of use to psychiatrists working in public health programs, and to those with teaching responsibilities. All workers in the field of psychiatric rehabilitation will also find it useful, not as a source book for guidance in program building but as a thoughtful assessment of the principles upon which rehabilitation rests and of the progress made to date. The book has more coherence and more substance than most conference reports.

WALTER E. BARTON, M.D.,
Boston 24, Mass.

HYSTERIE, REFLEX UND INSTINKT. By Ernst Kretschmer. (Stuttgart: Georg Thieme Verlag, 1958, pp. 148 Seiten, 2 Abbildungen, 8°, kartoniert. DM 9.80 (\$2.35),

Ganzleinen DM 12.80 (\$3.05.)

Ernst Kretschmer, who established his fame in the 1920's through his work on constitutional differences in schizophrenic and manic-depressive patients, discusses hysteria, reflex and instinct in this book. Hysteria is considered a reaction type which utilizes certain reflex and other biologically patterned mechanisms. Even a reader fully familiar with the German language finds it difficult to grasp the content of a not too well organized little volume. It is

impossible to convey the ideas to the American reader, since American psychiatry has followed such different trains of thought. The present volume represents the sixth enlarged and improved edition of a small volume which was published decades ago, and seems no longer entirely up to date.

CLEMENS E. BENDA, M.D.,
Waverly, Mass.

A TEXTBOOK OF MEDICINE. 10th Ed. Edited by Russell L. Cecil, M.D., Sc.D., and Robert F. Loeb, M.D., Sc.D. (Philadelphia: W. B. Saunders, 1959, pp. 1665, \$16.50.)

The sections on mental illness in such a deservedly popular textbook as "Cecil and Loeb" have an importance out of proportion to their brevity. This book is the first recourse of many students and graduates faced with a clinical problem. In general the sections on psychiatric disorders are well done. The authors of the discussions of neuroses and psychoses avoid the pitfalls of dogmatic, overclassified description and verbosely speculative interpretations. The common somatic symptoms which bring mentally ill patients to general physicians and specialists are properly emphasized. These symptoms test skill in diagnosis but of even more importance they challenge the physician not only to discover the patient's underlying personal difficulties but also to help him with them. The excellent section on the treatment of neurotic patients should encourage non-psychiatrists to develop their abilities in psychotherapy. In a future edition it would be worthwhile saying something about the place of the general physician in the care of chronically psychotic patients, particularly when increasing numbers are being discharged from mental hospitals to their homes.

KLINISCHE PSYCHOTHERAPIE INNERER KRAUKHEITEN. (Clinical Psychotherapy of Internal Diseases) (Berlin-Göttingen-Heidelberg: Springer-Verlag, 1959, DM 18.80.)

This small monograph, 68 pages long, consists of 6 lectures given at the opening of the Department of "Clinical" Psychotherapy of Internal Diseases at the University of Freiburg, Germany. (The term clinical would be best translated as: in a hospital setting.) The first 2 lectures were given by psychiatrists: J. H. Schultz, who is known by his book about the Autogenic Training, relaxation exercises as a form of psychotherapy; and, H. Goepfert, who wanders in his lecture through many fields

starting with the problem of the soma-psyche dualism and soma-psyche unity, discussing Freud, Weizsäcker, Jaspers, the existentialists, and the question whether there can be a psychotherapy of the psychoses. His leitmotif is: to learn from every school of psychotherapy. Though he is in full agreement with the desirable convergence of psychiatry and internal medicine he, understandably enough, sprinkles his lecture with warnings.

The next 4 lectures were given by 4 internists who worked in this newly opened department. They concern the scientific basis of a psychotherapy of internal diseases and several case reports. The lectures are on a high level, stimulating, speculative and hence, occasionally, confusing. It may be illustrative to mention that in the bibliography of the third lecture you find not only Franz Alexander's Psychosomatic Medicine but also Kant's Critique of Judgment. The authors stress that their research and their practical work are first attempts to clarify a new concept of the nature of disease; to pass, to return and to re-pass the frontiers between internal medicine and psychiatry. They also want to help the general practitioner in regard to understanding and treating his patients in a broader and more intensive way than before.

While I was reading the monograph I was wondering whether there are attempts in Germany, as they have now started here, to make the medical student familiar with the problems of psychosomatic medicine. But I did not find any mention of this.

Chicago, Ill.

PROGRESS IN NEUROLOGY AND PSYCHIATRY. Vol. 14. Edited by E. A. Spiegel. (New York: Grune & Stratton, 1959, pp. 656, \$12.00.)

For the fourteenth consecutive time a volume has been published as a review of the year's progress in the fields of neurology and psychiatry. In 36 chapters, 60 contributors have surveyed the current productions, making reference to over 4000 publications.

The subject is broadly divided into 4 sections: Basic Sciences, Neurology, Neurosurgery and Psychiatry. A compilation of this nature will serve a variety of purposes. As has been the case with previous volumes, it should find a broad use amongst those interested in neurology and psychiatry, either for the purpose of a leisurely ramble through the recent literature, or for the detailed examination of a more limited field of interest.

STANLEY E. GREBEN, M.D.,
University of Toronto.

VICTOR VANCE ANDERSON

IN MEMORIAM

VICTOR VANCE ANDERSON 1878-1960

On July 26, 1960, the Association lost one of its oldest Life Fellows and best known members in the death of Dr. V. V. Anderson in his 82nd year. He died at his home at Staatsburg-on-Hudson, N. Y. on the grounds of the School he had founded and loved and of which he had been active as Director and at work with the students until a bare two months before the end.

Dr. Anderson was born at Barbourville, Kentucky, December 26, 1878. He came from a family with strong medical traditions. His maternal grandfather, Dr. Oliver Harndon, was one of the pioneer surgeons in Kentucky, several of his uncles were physicians and he, himself, was the forty-second doctor in the immediate connection. Before he was out of grade school, his inclinations toward medicine were reinforced by working in the pharmacy of one of his uncles, who encouraged him in that direction. He attended Union College in Barbourville, where he achieved a distinguished academic record, and graduated from the University of Louisville Medical School in 1903. He was elected to the Honor Medical Fraternity, Alpha Omega Alpha. He entered general practice in Lynchburg, Virginia, but this was not a city practice as we understand it today, for Dr. Anderson described frequent trips on horseback or by horse and buggy into the neighboring country and the long hours spent on these calls in all sorts of weather and at all times of the day and night. He was known not only as a good diagnostician and therapist, but as a man vitally interested in his patients and in their everyday problems. With this background of experience it is not surprising that he should be specially intrigued by the understanding of human behavior offered by psychology, and in 1911 he went to Harvard University for training in psychiatry. In 1913, while he was on the staff of the Boston Psychopathic Hospital, he was selected from 120 applicants to become the Medical Director of the Psychiatric Clinics of the Municipal Court

in Boston, a unique position in the medical and legal world at the time. Three years later he obtained the Master's Degree in Psychology at Harvard.

In 1918, Dr. Anderson was appointed Associate Medical Director of the National Committee for Mental Hygiene. His first assignment was the direction of mental health surveys, which involved investigations of the incidence of mental disease and mental deficiency and the facilities available to deal with the problems. In 1922 he was placed in charge of the organization and development of child guidance clinics and was instrumental in the establishment of the first such clinics in several major cities in the United States. Two years later, in 1924, he left the National Committee to become Director of Medical Research for the R. H. Macy Department Store in New York City, a position which he held for 7 years. In the meantime, he had laid the foundations for the School which bears his name, not only figuratively speaking in the sense of developing an ideology and methodology, but also literally in the sense of purchasing land and buildings, collecting a staff and enrolling a few students. In 1931, he began to devote his full time and energy to the School and its progress continued to be his major interest and exclusive professional responsibility for the rest of his life. When he married the present Mrs. Anderson in 1930 after the death of his first wife, the School became a family project. For many years Mrs. Anderson has served as business manager, and Dr. Anderson's only daughter by his first marriage is the wife of the headmaster.

Dr. Anderson was the author of two books, *Psychiatry in Industry* and *Psychiatry in Education*, the first of which, published in 1929, has been translated into several foreign languages, including Chinese, and is still required reading in some colleges. He contributed chapters to *Why Men Fail* edited by Dr. Morris Fishbein and Dr. William A. White, *The Healthy*

Mind by Henry B. Elkind and wrote a number of papers on the various phases of psychiatry in which he was interested. He was one of those invited to contribute to the Centennial issue of the *American Journal of Psychiatry* in 1944, and wrote the article "Psychiatry in Industry" for that special issue. He was an active member of many scientific societies, including the American Orthopsychiatric Society, of which he was one of the founders and the first presiding chairman, the American Psychopathological Association, the American Academy of Child Psychiatry, the New York Academy of Sciences, the Progressive Educational Society, the Academy of Religion and Mental Health, and the New York Society for Clinical Psychiatry in addition to the local and state societies and the American Medical Association. His alma mater, Union College, honored him with the degree of Doctor of Laws in 1935, and in 1953 he was awarded the Fifty Year Service in Medicine Certificate of the Medical Society of the State of New York.

The varied aspects of Dr. Anderson's professional life might seem incongruous as a preparation for a major career in the application of psychiatry to education. Diametrically opposed to the idea of opportunism or purposeless drifting, Dr. Anderson had planned his future carefully and conscientiously. His fundamental interest in people, stimulated during his years of country practice, naturally led to the study of psychiatry, and his association with the courts to an especial concern with people who were poorly adapted to society. His activities with the Mental Health National Committee indicated the dimensions of the problem and focused his attention on children and adolescents rather than adults. Finally, his experience in industry showed him, on the one hand, why seemingly promising workers fell short of expectations and, on the other, what might be done with the apparently inadequate individual to bring out his highest potential. With this background, the step to the foundation of a school operated under psychiatric principles is not only logical, but, perhaps inevitable. Dr. Anderson loved flowers and poetry and sometimes described himself as a dreamer, but he was emphatic

on the subject of translating dreams into action and was an outstanding exponent of his theory.

His philosophy was essentially an expansion of the family doctor approach to human problems. Psychiatric therapy, for him, was not merely a matter of obtaining personality integration in an abstract sense. He believed that the well integrated person must be able to relate to and communicate with his fellows, that he must have a goal attainable only by strenuous effort and that, in the course of the struggle the patient's life should be constructive and productive. Although not pessimistic about adult problems, he felt strongly that the best opportunity for helping people was to be found by treating them in their earlier, more plastic years. This, of course meant the school years, and he conceived of education as a partner with psychiatry. He placed less emphasis on formal psychotherapy than on human associations or what is often called milieu therapy, feeling that the latter was a more effective tool for the majority of his patients, though he certainly used and did not disparage individual psychotherapy in specific cases.

Dr. Anderson will be remembered not so much for his professional achievements in a narrow sense, as for his character. The sterling qualities of honor and uprightness which distinguished him are becoming rarer these days, and are often less highly regarded than the more meretricious scientific or pseudo-scientific achievements which have been the sole claim to recognition of many lesser men. His monument is his ideals embodied in the Anderson School, not as a perishable structure of bricks and mortar, but as an expression of ideals which have influenced profoundly, and will continue to influence the minds and actions of its students. One of them has written a few lines quoted in the Headmaster's memorial address, which might well serve as an appropriate epitaph. "His complete freedom from malice or pettiness, his grandeur of outlook, his wonderfully clear sense of justice, always tempered by warm humanity and compassion will forever be his fond memorial in the hearts of all who knew him." *Requiescat in pace.*

Leslie R. Angus, M.D.

REVIEW OF PSYCHIATRIC PROGRESS 1960

HEREDITY AND EUGENICS

FRANZ J. KALLMANN, M.D.¹

Productivity in the gradually merging branches of cytological, microbial and biochemical genetics was characterized by judicious consolidation, technical realignment and selective expansion during the past year. With the consequent increase in the number of interdisciplinary research meetings and specialized genetic symposia came an equally sharp rise in the output of expertly edited conference proceedings, timely reviews and promising new research reports.

Published symposia covered a whole galaxy of topics, including cell culture and biochemical genetics (1, 25, 61, 71), the structure and functions of the cell and cell nucleus (4, 21, 40), the cellular aspects of immunity (72) and tissue homotransplantation (69), the genetics of cancer (57), aging (60) and congenital malformations (73), and the evolutionary, molecular and neurophysiological phenomena of behavior genetics (5, 19, 31, 63, 65, 66, 67). *Still unpublished* at the time of writing this review were the A.A.A.S. and A.P.P.A. symposia on the genetics of aging (Chicago, December 29 and New York, February 20), the latter with the reviewer's Samuel W. Hamilton lecture; the symposia of the American Eugenics Society on human twinning (Princeton, April 28-29), that of the Eastern Psychiatric Research Association on psychiatric correlates of enzymatic and hormonal disturbances (New York, November 5), and that of the New York Academy of Sciences on genetic perspectives in disease resistance and susceptibility (New York, November 17-18); also the general genetic symposia at the University of Utah (Salt Lake City, May 13-14), Western Reserve University (Cleveland, October 10-12), the

Mayo Clinic (Rochester, October 12), and the Kaiser Foundation Hospitals (San Francisco, October 14-15). An experimental teaching session in molecular and chromosomal genetics conducted jointly by A. Bendich and this reviewer was a special feature of the APA meeting at Atlantic City.

Worldwide cooperation in the rapidly moving field of cytogenetics was effectively promoted by an international conference held at the University of Colorado in April (2). By introducing a unified system for numbering the 46 human chromosomes, the so-called *Denver System*, the conference cleared up the terminological smog emitted by widely disparate classification methods.

In the group of cytogenetically identified *abnormalities in sexual development* due to the loss or addition of a sex chromosome, appreciable progress was made in extending the analysis of chromosomal disarrangements beyond the previously established triad of Klinefelter's syndrome (chromatin-positive males with testicular dysgenesis and an XXY-sex chromosome pattern), superfemaleness (sexually underdeveloped females with two sex-chromatin patches and three X-chromosomes) and Turner's syndrome (chromatin-negative "females" with ovarian agenesis and only 45 chromosomes including one X-chromosome). Ferguson-Smith's team (14) and Muldal and Ockey (41) described special Klinefelter variants with XXXY- and XXYY-sex chromosome complements, respectively, and Lanman, *et al.* (36) reported another case with 48 chromosomes (trisomy of a small autosome and an extra X-chromosome) that showed the symptoms of both mongolism and Klinefelter's syndrome. While the XXXY "males" with two sex-chromatin bodies were found to be grossly defective (IQ below 20), association of Turner's syndrome with mental

¹ 722 West 168 Street, New York 32, N. Y.

deficiency was observed by Fraser, *et al.* (17) in no more than 0.7% of mental defectives. Other informative reports included the history of a young girl with hemophilia who was classified as an XY-intersex, that is, a male who presumably underwent a process of sex reversal(44), and the case of a hermaphrodite who had a supernumerary chromosomal fragment in addition to a normal karyotype of 46 chromosomes including two X-chromosomes(13).

The cytogenetic classification of *mongolism* (trisomy of chromosome 21) was complicated by the observation that mongoloid symptoms may in some instances arise from reciprocal translocation between two of the smaller autosomes(15, 49, 50). In one case, a translocation seemed to have occurred between chromosomes 15 and 21. In another case, the apparently healthy father of a mongoloid boy had 47 chromosomes with trisomy of chromosome 19, or its equivalent in the Denver System, while the mongoloid patient was found to have a complement of 46 chromosomes with a translocation between two chromosomes 21. The same kind of translocation was observed in the family of an English woman who had three mongoloid grandsons, two brothers and their maternal cousin(6).

Reports on other types of *autosomal trisomy* in persons with multiple developmental defects (including Sturge-Weber's syndrome) also appeared in increasing numbers. Noteworthy in this category were the chromosomal disarrangements placed on record by Edwards, *et al.*(9), Patau, *et al.*(47), Hayward and Bower(30) and Sandberg, *et al.*(53). Even more remarkable were two Swedish cases with complements of 49 and 69 chromosomes, respectively(3, 16). Perhaps the most spectacular observation with far-reaching clinical implications was the detection by Tough, *et al.*(68) of extensive chromosome damage in two male patients who had received X-ray treatment for ankylosing spondylitis ("single dose of 250 rads limited to the skin over the spinal column").

While the output of *specialized textbooks* embodying these most recent advances in medical genetics lagged behind, commendable exceptions were new books on biochemical and radiation genetics by Harris

(29), Strauss(59), and Wallace and Dobzhansky(70), a German book by Lenz(38), a new edition of Stern's standard textbook on human genetics(58), and a concise introductory book for the general public by Penrose(48), despite its skeptical attitude toward the usefulness of twin studies. Introductions to quantitative genetics were contributed by Falconer(12) and Osborne and DeGeorge(46), and to behavior genetics by Fuller and Thompson(20). Provocative views about the influence of evolution and heredity on progress and survival in the current world scene were expressed by Hardin(28) in an absorbing book and by Muller(42), Simpson(54) and Wright(74) in some equally intriguing articles.

Prospects for the uphill struggle of *experimental genetics* to bridge the molecular and cellular levels of organization were scrutinized by Lederberg(37) in his Nobel Prize address from the standpoint of bacterial genetics, and by Ehret(10) on the basis of electron microscope studies. Promising steps toward the overall objective of genetic research—the mapping of human chromosomes through a full understanding of the biological activity of DNA—were taken by Sidman(64) with a highly refined organ culture technique (retinal dystrophy in mice), as well as by Bendich(64) through ingenious observations on biochemical changes which were seen on invasion of cultured human (HeLa) cells by extraneous DNA, either microbial or human (isotopically labeled DNA from human leukocytes and transforming DNA from pneumococcus). At the cellular level, variations in native resistance to certain infections (*i.e.*, pulmonary tuberculosis) were confirmed by the experimental work of Lurie(39) in rabbits as being determined by the activity pattern of reticuloendothelial cells.

In the sectors of *clinical genetics* bearing on psychiatric problems, the crop of research data which ripened to the point of publication was rather sparse last year. There were three investigations apiece dealing with Huntington's chorea(7, 43, 45) and phenylketonuria(22, 32, 51) and two serial studies of relatives of epileptics, one by Inouye(33) in Japan (families of 40 epileptic twin index cases) and the other

by Eisner and Livingstone(11) in this country (3,361 relatives of 669 epileptics). While the search for the primary biochemical defect in Huntington's chorea remained as inconclusive as that for readily identifiable chromosomal markers in phenylketonuria, the two epilepsy studies confirmed the operation of some genetic factor (biochemically unidentified) in certain "chronic" forms of the disease, especially in cases with a disease onset before the age of 16.

Other research reports dealt with the anthropometric characteristics of 44 young "war mulattoes" born out of wedlock to white Italian women during the occupation years(23); an Australian family with 11 cases of an apparently autosomal, dominant form of acute intermittent porphyria in three generations(8); a Swedish series of 119 same-sexed twin pairs with nocturnal enuresis in one or both partners, showing higher prevalence rates (a) for twins than for nontwins, (b) for two-egg than one-egg twins and (c) for girls with a male partner than for those with a female partner(26); and the second volume of population data (schizophrenia, mental deficiency, consanguineous marriages) for the two Swedish islands investigated intensively by the research unit of Hallgren and Sjögren(27). In a single pair of one-egg twins observed by Swanson(62), both partners made suicidal attempts, only one succeeding.

Regarding the genetic theory of schizophrenia, no decisive progress was made either in identifying the hypothesized mutational (metabolic) change in schizophrenics (18, 34, 56) or in disclaiming it altogether (24, 34). Rosenthal(52) found no statistical evidence for Jackson's nebulous "confusion of ego identity" theory(34) which would imply a higher frequency of the illness in twins than in non-twins, while Böök (34) considered the family and twin data accumulated over a period of more than 40 years as "consistent enough to provide a sound basis for the genetical theory of schizophrenia."

The "surging wave of advance . . . in revealing many of nature's deepest metabolic secrets"(35) was reflected by the fact that the 1960 Nobel Prize in physiology and medicine was awarded to another distinguished duo of experimental biologists, M.

Burnet and P. B. Medawar. The Albert Einstein Gold Medal was conferred on Leo Szilard for his outstanding work in nuclear physics and microgenetics, the 1960 Kimber Genetics Award on George W. Beadle, and the Samuel W. Hamilton Medal on this reviewer for research on the genetics of aging. The 1960 Galton Lecture was delivered by Eliot Slater on "Galton's Heritage"(55), while the 1960 R. Thornton Wilson Awards in genetic psychiatry were shared by Aaron Bendich and Sidney C. Werner(64).

NEUROPHYSIOLOGY, ENDOCRINOLOGY AND CHEMISTRY

O. R. LANGWORTHY, M.D.¹

Neurophysiologists are studying the mechanisms of motivation, drive, reward, punishment and emotion in a way exceedingly relevant to psychiatry. The terminology is complex and foreign to that of psychiatric literature. Summaries(1) and reports of symposia(2, 3) give the best introduction to this field. It will be recalled that the cerebral cortex of primates may be divided into a phylogenetically old, 2 cell layered cortex, a new or 6 layered cortex and an intermediate type. The new cortex growing up in the center of the old cortex has expanded greatly in primates and is related in great part to long distance sensory projection systems. It is accessible to exposure for experimental purposes and to its function has been attributed the superiority of man's intellectual capacities. This cortex is now somewhat deemphasized in experimental work as it has been possible to introduce microelectrodes in the other types of cortex and learn something of their activity. The old cortex, which Adolf Meyer called the purse string structure since it has been pushed down to surround the brain stem, is often known as the limbic lobe. Its limits are poorly defined but it includes the septal nuclei, subcallosal gyrus, olfactory tubercle, diagonal band, amygdala and hippocampus. This cortex has extensive reflex connections with the hypothalamus and brain stem through the medial forebrain bundle and fornix. Until recently its function has been a mystery. The intermediate cortex forms another ring structure between the old and new cortex. From a phylogenetic point of view it is a relatively recent development. Again its limits are hazy but it includes the cingulate gyrus, insula, hippocampal gyrus and the base and

probably a large part of the rostral portion of the frontal lobe. It appears to be related closely to the old cortex and serves to elaborate its activity.

The roles of the old cortex are now studied actively and certain useful hypotheses are emerging. MacLean(2) thinks that it is concerned with two basic life principles, self-preservation and preservation of the species. Thus stimulation of the amygdala and its related structures gives rise to alimentary automatisms such as chewing and retching from one point, whereas from another point it elicits searching, angry or defensive behavior that is required in the search for food and the struggle for survival. Stimulation of certain places in the hippocampus, cingulate gyrus and septum results in behavior conducive to preservation of the species, such as pleasure reactions, grooming behavior and sexual manifestations, including penile erections. Similar sexual responses can be obtained along projection pathways that follow a course from the septum through the medial preoptic region into the medial forebrain bundle. Leake(2) pointed out that repeated stimulation of this pathway does not lead to inhibition. Olds(2) reported that animals with an electrode in this region will self stimulate for periods of as long as 26 hours without any apparent lessening of the effect of the stimulus. When they stop, they stop because they collapse.

Lilly(2) discussed a small area in the septum, possibly representing the medial forebrain bundle in relation to lack of fatigue. A monkey with an electrode in this area will stay awake and self stimulate for 48 hours without sleep. The sexual system here seems to be combining the effect of the powerful energizing avoidance system and the extreme pleasure of the rewarding sys-

¹ The Phipps Clinic, Johns Hopkins Univ., Baltimore, Md.

tem. Olds(2) spoke of a common denominator of function in this area and the relation of all drives to a common mechanism of reinforcement. Slight movement of the electrode in the hypothalamic, midbrain or limbic region can bring about sharp differences in elicited behavior, but there is always a positive reinforcement of behavior. Olds (2) has shown that a region yielding a high self stimulation ratio runs in a broad path along the medial forebrain bundle region in the ventrolateral floor of the hypothalamus. Bond(2) thinks of the septum as a general system for energy coming upward and going to various areas that participate more selectively in different types of behavior. Olds stated that anatomically the septal area is a junction on a two way route between amygdala and hypothalamus and also a junction on a two way route between hippocampus and hypothalamus.

The small portion of this review related to endocrinology may follow here, related to the neuroendocrine aspects of sexual activity. Sawyer, *et al.*(1) studied the neural events leading to the release of gonadotrophic hormone from the pituitary producing ovulation. In the rabbit, excitation of vaginal receptors causes ovulation. Such stimulation is followed by alterations in brain wave activity in the lateral portion of the hypothalamus, preoptic region and in the frontal and limbic cortex. This activity begins a few seconds after the stimulus and continues for several minutes. In animals with a sexual cycle, similar changes of electrical potential occur preceding ovulation. This modification in the lateral preoptic region appears to be related to sexual activity since it could only be recorded during spontaneous or induced estrus. Ascending reticular fibers from the brain stem appear to excite neuroendocrine hypothalamic mechanisms. Ovulation may be blocked by a variety of drugs which appear to impair excitability of the reticular system. Both cholinergic and adrenergic blocking agents prevent ovulation. The cholinergic components act earlier and perhaps involve the afferent pathways from the vagina. The adrenergic component probably represents the final hypothalamic link with the hypophysis.

Green, *et al.*(3) have observed the de-

velopment of hypersexuality after lesions of the pyriform cortex beneath the basal amygdaloid nuclei in the old cortex. This appeared not so much an actual exaggeration of sexual behavior as a loss of the animal's capacity to distinguish its special territory from the ordinary environment and to adapt its behavior accordingly. There seems to be no evidence that the hypersexuality induced by lesions in the pyriform cortex has anything to do with endocrine mechanisms. These observations perhaps open the problem of territoriality to experimental study. This is a subject of special importance in human relationships.

Before leaving the hypothalamic area its relation to appetite may be mentioned(2). This appears to be a food intake mechanism in the lateral ventral hypothalamic region. After injury to this area extremely hungry animals refuse to eat when presented with food. After injury to a closely related system a satiated animal still makes chewing movements and takes food into the mouth over and over again. Medial lesions in the hypothalamus make the animal eat when he is not hungry and lateral lesions make the animal refuse to eat when he is hungry. In both cases the animal is more prone to be guided by taste than any drive to eat. It is impossible at present to relate the problem of anorexia nervosa to these findings.

Psychiatrists may be interested in basic physiologic concepts concerning the nature of inhibition in the nervous system. It appears that certain neurons with short axons, internuncial cells or type II cells of Golgi, have an inhibitory function and give off a special chemical mediator at their terminal synapses which is inhibitory. This causes a hyperpolarization of the neuronal membrane which is the reverse from that associated with excitatory reaction or depolarization. This theory was first glimpsed by intracellular recording from spinal motor neurons. Renshaw(1) found that a two neuron reflex arc was inhibited by stimulation of the ventral root. He proposed that this was due to antidromic stimuli evoking a discharge of the interneurons. Eccles(1) called the specialized cells mediating the inhibitory influence Renshaw cells. There is a belief that an identical chemical transmitter is liberated at all the functional terminals of

a single neuron. Thus the synaptic transmitter from motor axon collaterals to activate Renshaw cells is the same transmitter which activates muscle cells at their peripheral terminals, namely acetylcholine. The insertion of an intermediate neuron in the circuit is a device to change the chemical mediator acting on the next or the inhibited cell.

Chemistry may be represented in this review by a consideration of the nature of the inhibitory transmitter. Florey and McLennan(1) found a Factor I which caused inhibition of the stretch reflex. It is not the same as acetylcholine or the postulated sensory transmitter. Factor I remains in solution after treatment which precipitates histamine, noradrenaline and adrenalin. Strychnine formerly considered as a convulsive drug blocks Factor I and wipes out the inhibitory action of the Renshaw cells. Investigators are now working with gamma-amino-butyric acid (GABA), which is found in brain extracts and forms part of the inhibitory factor. The action of GABA exhibits many qualities of nerve cell inhibition. The use of GABA applied topically to the surface of the nervous system has demonstrated the absence of inhibitory neurons in the cerebellar cortex. It has also been proposed that there is an absence of Renshaw cells relaying the inhibitory transmitter in the hippocampus. This would tend to explain the low threshold of the hippocampus for seizure activity. An outstanding feature of GABA is its predelection for dendritic synapses.

Changes in electrical potential recorded in brain wave tracings has become an important indicator of conditioned reflex activity and permits evaluation of events not only in cortical but also in subcortical structures. Yoshi(1) found that the conditioned response appears first in subcortical structures, particularly the midbrain reticular formation, and is much larger and longer lasting there. In early stages the conditioned response is diffuse but later the thalamic reticular system filters out widespread impulses so that they reach only the localized cortex where the effect of the unconditioned stimulus occurs. Morrell and Jasper(1) used visual stimulation as an unconditioned stimulus in forming temporary conditioning. The light was repeatedly preceded by an

auditory or tactile stimulus to which the animal had previously become adapted and did not respond. A generalized potential change in the cortex upon auditory or tactile stimulation provided first evidence of conditioning. When the reflex was further developed the auditory or tactile stimulus provoked only local activation of the visual cortex.

Worden(2) found that potential changes in the electroencephalogram could be elicited at all levels of the acoustic pathway in response to conditioning. He planted multiple bipolar electrodes chronically along the auditory pathway in the cochlear nucleus, trapezoid nucleus, inferior colliculus, medial geniculate, auditory cortex and reticular formation. Since the animals were still alive the position of the electrodes had not been verified. Using a constant tone of several seconds duration as a signal the animals were taught to press a lever to obtain food. The cats were also trained to a negative auditory stimulus which meant that the pedal would not deliver food. The cats showed signs of learning on the third day of trials and potential changes were noted in certain leads following the auditory signal. On the sixth day of training to the positive stimulus large potential changes were present in all leads. There were correlations between the evoked potential changes in the different leads and the individual behavioral events so that the responses from different leads varied from time to time. Extinction of the conditioned reflex increased the amplitude of evoked responses both to the positive and negative stimuli. During learning the positive stimulus evoked a larger response than the negative, whereas, in extinction the negative was greater than the positive. Galambos(2), in commenting upon this work, pointed out that this study demonstrates clearly that brain changes in conditioning are by no means limited to neocortical structures.

ELECTROENCEPHALOGRAPHY

W. T. LIBERSON, M.D., Ph.D.¹

Recently papers on EEG and conditioning have trickled into the neurophysiological literature in increasing numbers. In the past two years there has been a "paper explosion" in this field. International symposia with large East and West participation were held in the U.S.A., France and U.S.S.R. Countless papers and reviews were prepared (24, 38). This limited review will have to be once more constricted in its scope, covering, this year, conditioning and EEG. One important contribution confirming previous findings (18) in a more controlled experiment should, however, be noted (44). Intravenous pentothal was administered to carefully selected patients with either schizophrenia or depression. The resulting increase of EEG activity, particularly in its fast range, was significantly higher in schizophrenics. Whether depressed individuals are characterized by a decreased drug-induced electrogenesis when compared with normals or the schizophrenics have a true increase of the electrophysiological output is still to be investigated. Previous studies suggest that the latter is correct (18).

CONDITIONING AND EEG

1. Generalization and Concentration: Early studies suggested that a generalized cortical desynchronization is seen at the onset of conditioning. This desynchronization is later "concentrated" in the region related to unconditional stimuli (UCS): occipital area in conditioned alpha-blocking; contralateral motor cortex in leg withdrawal reflexes. Diffuse evoked potentials and desynchronization could be induced by conditional stimuli (CS) in many structures (generalization). Certain cortical areas are more suited for associating stimuli than others. Secondary potentials evoked by flicker were recorded in cats in the sensorimotor, primary visual and associative areas, but not in the primary auditory cortex (15). The motor cortex shows secondary potentials evoked by all sensory modalities and,

therefore, represents an "associative cortex" par excellence. In man, pairing a conditional stimulus (CS) with fist clenching elicits a conditioned local depression of the "wicket rhythm" in the contralateral central region. This is preceded by a phase of generalized desynchronized response (15). Desynchronization and evoked potentials were found at the beginning of learning in the hypothalamus (26, 37), thalamus (41, 49), and reticular formation (21, 49). Regular rhythmic activity could be observed in the medial thalamus and slow rhythm in the n. centralis lateralis (43). In the dorsal hippocampus, 6 c/second activity is generally found at that stage (2, 20, 21, 49). However, approach behavior is more prone to be associated with such activity than other behavior manifestations (searching head movements) (2). Such hippocampal activity may reflect reticular formation activation (20, 21). When CR's are established, desynchronization may persist in the cortex and hypothalamus where it may shift in time toward the onset of the CS (34). Slow waves may appear instead (17, 27, 28, 42, 49). Certain thalamic nuclei (VA) may become involved in CR's, and 4 c/second activity appears (47, 49). The same is observed in the reticular formation: slow activity may appear at this stage; evoked potentials may be suppressed here (particularly in avoidance) or increased (in approach) (24, 49). Hippocampus may also show a variety of responses. The negative stimuli during differentiation may elicit either desynchronization or slow activity, or regular slow rhythm.

While during the initial phases of conditioning, the effects are wide-spread and relatively constant, during the second phase of conditioning, less constant phenomena are observed. In one study (4) using cats, no local response was found in conditioned arousal by a tone paired with electric shock to the leg; electrical responses decreased by repeating CR's. The lack of a constant relationship between the EEG arousal and CR's is not surprising since cortical desyn-

¹ VA Hospital, Hines, Ill.

chronization does not always signify an excitability increase(30). In defensive CR's, despite diffuse cortical desynchronization, thresholds established by electrical stimulation decrease only in the contralateral motor cortex. Also, two desynchronizing systems were suggested for the reticular formation (3); one related to food-getting and the other to defensive reflexes, corresponding to approach-avoidance dichotomy. Chlorpromazine affecting only defensive system, permits dissociation of these effects. Also, when one finds a hypothalamic "point" facilitating food-getting behavior, its stimulation automatically inhibits defensive reflexes(19, 20).

EEG changes differentially found in a variety of cortical and subcortical areas during different phases of conditioning suggest that "closures" of temporary connections may occur in the subcortex, rather than the cortex(15). The following additional procedures have been used :

A. Frequency-Specific EEG Changes : When a rhythmic stimulus (flicker) is used as CS or UCS, driven responses in the EEG are facilitated and often new "injected" frequencies may be revealed in the tracings between conditioning trials. Recording these "labeled"(24, 25, 26) frequencies facilitates the study of the destiny of a CS in the cerebrum. All workers agree that the appearance of these new EEG frequencies are associated with early conditioning and that they tend to disappear at a later date. However, for some, there is a final disappearance of these rhythms when the conditioning is well-established(31); for others, they concentrate in a few critical structures, at least in the approach behavior (not in avoidance)(24). Thus, a 3 to 4 c/second flicker paired with electrically induced leg withdrawal, elicits driven responses in both visual and contralateral sensorimotor cortex (35). "Labeled" rhythms were found in the cortex, reticular formation, and hippocampus during initial phases of food and avoidance conditioning but they shifted to the visual system and the n. ventralis anterior when conditioned behavior was well established (24, 25, 26). In another study, during conditioned avoidance behavior, both "driven" and "injected" resting rhythms were found in the cortex and hippocampus, but they disappeared when the conditioning was

well established(31). They may reappear when CS's are not reinforced(35) (see also 46, 50). They seem to be facilitated by processes of differentiation(10, 29). It seems, therefore, that these rhythms are used by the CNS for stimulus-identification, particularly during stressful situations(31). It is not certain whether they are required to carry out a well established CR.

B. Laminar Studies and Microelectrography : During initial stages of training, single cell activity to visual CS is induced in visual cortex, hippocampus, and reticular formation(37). According to another study, however, the formation of the motor CR is always associated with a decrease of unit activity in the motor area(23). When the reflex is well established, activity predominates in layer 4 (receptor) of the CS region and in layer 5 (effector) of the motor cortex(39, 40). A beautiful analysis of the phase reversals in the dorsal hippocampus during training was described(2).

C. Cerebral Stimulation : Attempts to study conditioning by direct stimulation of the cerebrum are increasingly successful. Stimulation of cortical areas was paired with leg withdrawal and this made a successful CR(12). This study showed an easy transfer of conditioning to the sensory stimuli of a modality corresponding to the cortical region stimulated, or to the cortex of the opposite hemisphere. The latter can be observed after sectioning the corpus callosum. Sectioning cortex around the stimulated areas does not prevent the appearance of CR, but undercutting this region, does. This suggests that the temporary pathways are centrifugal. Although the initially stimulated region may be ablated, the CR persists. These studies were extended to cerebral stimulations for both CR and UCR. Thus, the latter can be realized by stimulating the motor cortex(14).

In a satiated animal, a food CR could be established only when corresponding points in the hypothalamus were stimulated(45). After repeatedly pairing a CS for food-getting (3 c/second flicker) and hippocampal stimulation at the same frequency, the latter applied alone induces the food CR. This CR may be partially differentiated from the electrical stimulation applied to the opposite hippocampus(31).

2. *Participation of Subcortex in the Genesis of Conditioning*: These general findings show that subcortical regions may participate in the formation of CR's. On the basis of analogous data and in view of the convergence of many sensory modalities upon the neurons of the non-specific systems of the mesencephalon, diencephalon and rhinencephalon a theory was proposed that the "closure" of the temporary connections takes place in these regions preferentially (15). One related argument(5, 6) is that since many CR's are associated with emotional components, it is reasonable to assume that additional closures will be established in the limbic system and hypothalamus, the main closures remaining in the cortex. Direct experimentation in this field was developed using electrophysiological procedures in addition to ablations. The results of the latter were both confusing and illuminating. Practically any higher cerebral system could be eliminated in several stages without irrevocably suppressing the ability of the animal to form temporary connections of some sort. Massive bilateral lesions in the reticular formation do not suppress EEG arousal(1, 11) visual pattern discriminations and avoidance reactions. When intracerebral reflexes are formed by using stimulations of reticular formation as UCS, the ablation of the stimulated region does not suppress CR (41). Transcallosal connections are not indispensable for generalization(12). Bilateral hippocampal lesions do not block avoidance behavior in cats(20, 22), although they impair auditory CR. However, lesions of centre median may impair CR's (13, 48). Ablation of the posterior hypothalamus does not(13).

Electrophysiologically, attempts were made to produce temporary physiological dysfunction in various regions by either setting a spreading depression(7, 8, 9), or convulsive discharges(16, 20, 32, 33, 36). Hippocampal seizure discharges temporarily suppress CR's(16, 20). However, CR's may be formed in cats despite training carried out during hippocampal discharges. Fixation could be established in rats despite the hippocampal discharge preceding the training by a few minutes(32). However, if this interval was reduced to less than five min-

utes, fixation could not be formed after generalized convulsive discharges. The usual behavior could not be elicited in fixated rats following either generalized or hippocampal seizure discharges at the beginning of the series of trials. However, resistance to the disturbing effects builds up during the consecutive trials insofar as approach behavior is concerned and not in avoidance(32). All in all, it becomes obvious that during early conditioning, widespread connections are formed in a parallel fashion and it seems that the original diffuse desynchronization and generalization of evoked responses somehow participate in this process.

3. *Circuits for Learning*: As a basis for new experiments, hypothetical circuits for conditioning learning have been proposed. Attention was once more drawn to the extraordinary possibilities of a neural reticulum to converge a mass of information to single neurons(15). The proposed diagrams, however, do not contain specific components, which will make a non-reinforced CS to become a conditional inhibitor, a requirement which any diagram of this sort should satisfy. However, the French physiologists do recognize the possibilities of including such connections in their diagrams which is reticular-formation-centered. From Georgia, U.S.S.R. comes the most elaborate attempt to date to propose a blueprint for conditioning, but it is cortex-centered(5, 6). Briefly, an activity of high order is ascribed to stellate cells capable of sustained self-reactivation because of the considerably developed perineural reticulum. Inhibition would be effected through electrotonic activity of apical (generalized inhibition) and basal (limiting focal excitatory processes) dendrites. Reverse connections play a dominant part in this theoretical construction.

The same monograph contains remarkable experimental studies showing the importance of the space factor in conditioning. We believe that space and time factors should be given more consideration for the understanding of conditioning. Experimental analysis shows that potentials evoked by either regularly repeated flashes or intracerebral (hippocampal) stimuli are progressively modified as to their temporal course, seemingly adapting themselves to

the frequency of stimulation(31). It is this kind of basic EEG studies which seem to hold great promise for the future understanding of brain mechanisms permitting an animal to anticipate an event within a certain modality system at a certain time and at a certain place.

CLINICAL PSYCHOLOGY

FREDERICK WYATT, Ph.D.¹

More books are published every year concerned with the status and implications of psychoanalysis. Each of them in its own way expands upon the significance of that subject for the modern world. It sometimes looks as if Jones's impressive biography (17) had given the signal for a continuous evaluation of what psychoanalysis is, *sub specie aeternitatis*, or at the very least what it has contributed to civilization. If the cue for the accession to universal fame is seen in the volume of publicity, and especially in an ever-extending effort to relate the new protagonist to every conceivable facet of culture, then psychoanalysis has at long last arrived. The books of which I am speaking must be clearly distinguished from reports about the advances of psychoanalysis as part and as a system of psychology. The contributions here to be reported on are by nature theoretical and tend to be interdisciplinary in orientation. The emphasis is, however, not on the theory itself—at any rate, not on the theory alone—but on its application to a much more general purview (9, 14, 21, 25, 34). The new genre which so vigorously multiplied in the last few years has its risks and problems; but it also serves a function that may justify its frequent vagaries and pitfalls. All great interpretations of the human condition contain and conceal more than their authors could have been aware. In fact, the enduring greatness of scientific as well as of literary works can well be assessed by the scope of what is at first latent in them, but soon begins to show its stimulating and germinating power every-

where. Any monumental new insight like psychoanalysis is bound to affect the intellectual orientation of man far beyond its original scope. When Freud likened his work to that of Copernicus and Darwin he was no more than realistic, and simply foretold the task ahead of the next generation of Western intellect. The liabilities of those who respond to the challenge are as obvious as they are, historically speaking, inevitable. The ones who examine psychoanalysis with adaptation to new purposes in mind are as prone to compound identification with appropriation as were those who examined evolutionary theory a century ago. In the process, the borderline that divides exploration from exploitation gets so blurred that it can usually be redrawn only after it has been re-surveyed by a later and more detached generation.

The recent trend in the adaptation of psychoanalysis to broad cultural perspectives was ushered in by Marcuse (21) whose point of departure is Freud's cultural pessimism. Marcuse's point of reference is an economic interpretation of social development which he ultimately holds responsible for the evils of conflict and repression. Brown (5), a cultural historian, has more recently moved in the same direction. He is concerned with Freud's ideas on the life- and death-instincts (Eros and Thanatos) and on sublimation, and follows up their workings in history through an examination not so much of history itself but of the interpretation of history and life by various great men. Civilization is viewed as a sequence of deepening repression, and

¹ Ann Arbor, Mich.

Brown's exhortative concern is with the lifting of it. Rieff (29) stays with the present. His attempt is to cull from Freud's discoveries the outline of a new morality. Riesman (30) through a brilliant content analysis of Freud's work already pointed several years ago to the values and sentiments inherent in it. Nelson's collection (24) contains a great diversity of testimonials as to Freud's significance for the century, and shows clearly that psychoanalysis has long transcended its place in psychology and psychiatry. A survey of this expansion is also the subject of a series of seven essays contributed by British psychoanalysts and edited by Sutherland (34). The participants in a very extensive symposium edited by Sydney Hook (14) examined the scientific status of psychoanalysis, and in the course of it produced one of the most interesting and intellectually exciting books in this field. The scientific status of psychoanalysis is habitually belabored by critics who prefer to express their distaste of it in this manner, yet wish to protect their objectivity by ignoring those aspects of psychoanalysis which do not fit their preconceptions. Nevertheless, the unique status of psychoanalytic concepts and the logic peculiar to them poses a problem of vital relevance when it is approached in a realistic and informed frame of mind. A similar symposium edited by Bellak (3) addresses itself to this purpose by examining the concepts of libido theory, of the Unconscious and of psychic structure.

Two outstanding issues of a new psychological monograph series pertain to psychoanalytic theory: Erikson's (10) brings together several important papers of his on identity and the ego, published before. Rapaport (26) offers a terse discourse on the structure of psychoanalytic theory with brief but incisive discussion of its critical problems. The complex tasks of learning and of teaching psychotherapy are at long last treated in a systematic discussion by Ekstein and Wallerstein (9). Fraiberg's book (11) on the psychological understanding of early childhood, among the best available on this subject, should appeal to the professional and non-professional reader alike.

The study of the sociological determi-

nants of mental illness, begun by Hollinshead and Redlich, is continued into an examination of family and class by Myers and Roberts (23). The mental hospital as a small society, and the effect of its covert emotional structure on the patient is the subject of a monograph by Caudill (7). The methodology of research on the effects of various kinds of treatment is dealt with in a procedure-oriented quasi-textbook form by Reznikoff and Toomey (28), and from a multiple point of view, both descriptively and systematically, by Chance (8). Jahoda's book (15) on what is, and on what should be called, *mental health* provides an exemplary discussion of questions which are very far from being merely theoretical or semantic.

Holt and Luborsky's two volumes (13) report on the criteria for the selection of psychiatric residents and on the theoretical and methodological problems of defining them. Their books present one of the best achievements in recent psychological assessment (that is, the diagnostic study and evaluation of personality traits and abilities). Among books on diagnostic tests, two volumes on the Rorschach Test should be mentioned: on adolescents by Ames, Metraux and Walker (1), and on elementary school children by Ledwith (18). There is a new book out on the Szondi Test, by Szondi, Moser and Webb (35). Porteus has written a new book on his Maze Test (25) which should be much more widely used, broadly applied and studied than it is at present. A series of interesting new tests aiming at the measurement of social adjustment together with that of intelligence are described by Leiter (19). For a more comprehensive view of clinical psychology two books should be consulted: Brower and Abt's third volume of *Progress in Clinical Psychology* (4), including among others an intensive discussion of the state of diagnostic testing by seven experts; and Beck and Molish's reader (2), a collection of papers in clinical psychology of great historical and topical breadth.

Among the ever increasing number of new books in the social sciences, the following may be of interest for the psychiatric reader: a highly original sociological approach to the problem of identity, its trans-

formation, continuity and change, by Strauss(33); a systematic introduction into sociology, outstanding by its clarity, by Johnson(16); a comprehensive book on the social psychology of groups by Thibaut and Kelley(36); and a very useful compilation of research methods in social relations by Selltitz, Jahoda, Deutsch and Cook(32). On the subject of communication two titles present themselves: one more specifically oriented toward psychopathology, stressing experimental studies on a variety of levels, by Hoch and Zubin(12); and a more discursive one oriented toward ideas originating from a variety of fields, by Carpenter and McLuhan(6). Mandler and Kessen(20) deal instructively with the logical and epistemological qualities of psychological concepts. Rapoport presents a mathematical method for conceptualizing human conflict based on Game and Decision Theory(27); Roe and Simpson a collection of papers on the evolutionary origins of human behavior(31); and, finally, Murray(22), a series of papers organized around the theme that myth is not only an historical form but a perpetual aspect of experience, and thereby an elementary determinant of human conduct.

CLINICAL PSYCHIATRY AND PSYCHOTHERAPY

NOLAN D. C. LEWIS, M.D.,¹ AND PAUL H. HOCH, M.D.²

It is obviously impossible in the space at our disposal to include all of the research and clinical contributions of importance that have been published during the past year. It is, therefore, our task to select rather arbitrarily a limited number of those that have come to our attention, at the same time, attempting to present items with some spread over the clinical area assigned to us.

As should be expected, schizophrenia because of its position in the frequency of mental disorders, remains of prime interest in clinical psychiatry. Chapman, *et al.*(1) submit a very comprehensive thesis dealing with human ecology of disease, impaired organ functions and tissue damage. It presents a theory of adaptive reactions in general, and those in the schizophrenic process in particular, and Searles(2) devotes an excellent essay on the dynamics of integration and differentiation in schizophrenia; a theoretical exposition of phenomena which in clinical practice are closely interwoven.

A discussion of a central dynamism in chronic schizophrenia is discussed by Van Dusen(3) with emphasis on the clinical

phenomenology with case examples. He points out that a thorough phenomenological exploration becomes effective psychotherapy with the chronic type of patient whose symptoms are stereotyped. The semantics and context of the schizophrenic's language is discussed by Ferreira(4) a difficult subject which he attempts to clarify and to establish a theoretical basis for the bizarreness of the language used by schizophrenics, and Lewis and coworkers(5) made a preliminary study of abstraction ability and orality in schizophrenics utilizing 30 patients and 30 matched controls utilizing a proverbs test. These studies confirmed the relative inability of the patients to abstract such material, particularly in abstracting oral as compared to anal and phallic proverbs. No such differences were noted in the control subjects.

Johnson(6) reported his investigation of the moral judgment of schizophrenics. Forty-five patients and 15 controls were studied by Baruk's Tsedek Test of Moral Judgment as a basic procedure. The judgments made by schizophrenics differed from the non-schizophrenics in social thinking. It was one of deviancy reflecting tendencies toward social detachment, and egocentric concerns while normals made humanitarian judgments pre-

¹ State Bureau of Research, Princeton, N. J.

² Department of Mental Hygiene, State of New York ; College of Physicians and Surgeons, Columbia University.

dominantly. Beck(7) in an interesting study with theoretical components presents in some detail the phenomenon of affect autonomy in schizophrenic patients, and Ehrental and Jenney(8) investigated the time sense in schizophrenics. They discuss the various conceptions of time and found this sense disturbed in a number of patients. Some gave their ages to be those they were at the beginning of their illness. Modell(9) made a systematic study of schizophrenic patients with auditory hallucinations. Tape recordings were made of the subject's descriptions over a long period of time, and it was possible to draw some pertinent generalizations regarding the mechanisms involved.

In a study of homosexuality and paranoid schizophrenia Klaf and Davis(10) made a survey of 150 patients and an equal number of non-psychotic controls. The findings are discussed in relation to Freud's hypothesis concerning the development of paranoid symptoms. They conclude that additional thorough scientific studies will have to be made for the verification of the theory that paranoid mental symptoms develop as a defense against emerging homosexual trends. Utilizing human figure drawings by 18 schizophrenic and 18 normal adults Machover and Liebert(11) made an extensive study of these two groups of subjects. Drawings were produced with and without L.S.D. administration revealing a variety of differences which are described and analyzed. An interesting investigation, attempting to detect factors having prognostic significance in both acute and chronic forms of schizophrenia, was reported by Walker and Kelley(12) the types of symptoms, various social and other environmental factors were considered, as well as the length of, and type of therapy afforded. It is of some interest to note that they found the Hooper Visual Organization Test (V.O.T.) a failure as to its prognostic value with both the acute and chronic types. Salzman(13) reviews some of the pertinent studies that have been made on the dynamics of paranoia and paranoid states illustrated by case material pointing up the theoretical and therapeutic aspects of the condition. Three cases of Ganser syndrome are described by May and co-workers(14) in connection

with a constricting but protective life situation which is preferred by the subject to the hazards of freedom. Acute symptoms were precipitated by the threat of expulsion from the first type of environment into the second. This Ganser reaction is therefore released by a situation which is the reverse of other reported cases.

Bartemeier(15) presents cases to show the predominating symptoms of borderline disorders where anxiety may have served to prevent further development of the psychosis. The patients were considered borderline as they had neither hallucinations nor delusions and were not legally committable. Forrer(16) discusses instances and presents cases of hallucinatory experiences in non-psychotic persons, emphasizing that benign hallucinations are not infrequent in those hospitalized for medical or surgical reasons. A review of the concepts in the literature and a discussion of the factors involved in serious suicidal intent with case illustrations of the common features characteristic of these patients, which appear to constitute a special syndrome, has been published by Stone(17), also a review of the literature and a study of cases of adolescent and young adult self mutilation incidents in a general psychiatric hospital was made by Offer and Barglow(18). These self attacks occurred in severe character disorders, in schizophrenia and in borderline states. They are interpreted as "suicidal gestures" rather than genuine attempts. The incidents have a contagious quality through imitation and identification.

Among the accounts of perversions is the informative description of the mechanisms of aggression and forbiddenness in creating voyeurism published by Yalom(19) with case histories and psychodynamic comments. Wahl(20) has reported the psychodynamics of two cases of consummated maternal incest. While father-daughter incest is not rare, mother-son incest is either exceedingly rare, or at any rate is rarely reported; therefore, these two cases are of particular interest psychologically. Regarding family neuroses, Erenwald(21) reports 4 case histories including one family pedigree covering 4 generations. The study focuses on the potentially communicable nature of disturbed interpersonal attitudes.

Norris(22) discusses the possible prenatal factors in intellectual and emotional development. Several of these are pointed out, but it is emphasized that investigations on prenatal influences are still new and speculative. If they are eventually confirmed they will serve as a "first line of defence against mental illness." There are obviously some psychophysiological influences that exert emotional and physical stress on the prenatal organism. Hoffman(23) attempts a philosophic analysis of attitudes toward psychiatry, nature, and science, to clarify the meaning of concepts and the terms used to express them. He points out that the terms used in labeling personalities cannot be defined scientifically and that their use often confuses the issues. Llopis(24) of the Psychiatric Clinic of the Provincial Hospital of Madrid has presented an essay describing in detail his unique "Concept of an Axial Syndrome Common to all Psychoses." It is based on a great deal of experience.

PSYCHOTHERAPY

A comprehensive overall review by Appel(25) states that physicians and surgeons will be called upon in the future to do more psychotherapy than in the past or present. He outlines the various types of psychotherapy that can be applied by the general practitioner. He presents an illustrative case history. Lichtenberg and associates(26) offer an analysis of various types of therapy in terms of their utility in practice and clinical settings. It is a classification of therapeutic procedures and techniques according to degrees of mutual-achievement strivings as related to type and severity of the mental disorder. Whitehorn and Betz(27) report a continuation of their pioneering studies of the physician-patient relationship in therapy, showing how the therapist is a crucial variable in the results of treatment with schizophrenics and neurotics. These unique studies have a fruitful predictive value. Bellak(28) deals with the treatment of schizophrenia and psychoanalytic theory with their interactions. It involves mainly the situation of ego strength and ego functioning. Any treatment must act toward the improvement of these. Schizophrenia is interpreted as global disturbance of the ego function, of a severe nature. Ansell(29) in

an essay reviews the ideas and ideologies in psychotherapy, indicating the directions in which therapeutic attitudes are moving, particularly in psychoanalysis, and Lehrman(30) has examined critically the lack of precision in psychoanalytic procedures reviewing a number of published opinions by various authorities, from which he concludes that scientific precision has often been consciously excluded from classical psychoanalysis, that it has several aspects of religion and has tendencies to "defensive secrecy and arrogant elitism." Novy(31) analyzes religion in relation to psychoanalysis and other psychotherapies pointing out the issues and the complications of the relationship.

Important experiments in hypnosis reported by Kaplan(32) showed that it does not completely remove the perception of pain. It is only displaced or repressed by an artificially induced dissociative state. The subject feels physical pain but does not consciously realize it. It is concluded that chemical agents acting at the neurophysiological level are more appropriate to use, when possible, than hypnosis. Meldman(33) reports a case of personality decompensation after hypnotic symptom suppression. In his opinion, while hypnosis is effective for symptom removal, it is contraindicated when the symptom is related to an obsessive-compulsive syndrome or to a serious personality character defect or to a defective ego. Careful histories must be taken and a diagnosis made to determine the type of therapy to be applied.

Doshay(34) advocates psychotherapy as an adjunct in the treatment of paralysis agitans. Regardless of the type of drug and physical measures required, psychotherapy is needed to integrate the therapy. It is important in this long term disorder to gain and maintain the confidence and cooperation of these subjects and to support them psychologically. Strupp(35) has published an excellent discussion of the nature of the psychotherapist's contribution to a treatment process.

Group psychotherapy is very active in many centers over the United States and is definitely on the increase, and there are some interesting publications. Berne(36) discusses psychoanalytic versus "dynamic"

group therapy. He points out that the evidence in the literature is insufficient to justify applying the term "psychoanalysis" or its cognates to group therapy, but that "dynamic group therapy" should be appropriate and enough. Straight(37) made a follow-up study of 24 hospitalized patients—14 of whom had received group therapy and 10 utilized as controls. Evaluation was made of the level of social functioning. The evidence for better adjustment was in favor of the group treated patients. Finally, Bennis(38) presents a critical review of group therapy research emphasizing and analyzing the difficulties and the realistic and emotional reasons for the lack of collaboration in research in this field.

Among the informative books of the year bearing on the topic of this section are :

PSYCHIATRY : DESCRIPTIVE AND DYNAMIC. By Jackson Smith. Baltimore : Williams and Wilkins Co., 1960.

PSYCHOTHERAPY : A COMPARATIVE ANALYSIS OF CLINICAL PICTURES. By Carl Frankenstein. New York : Grune and Stratton, 1959.

SHAPES OF SANITY. By Aneslie Meares. Springfield, Ill. : Charles C Thomas, 1960.

FREUD AND DEWEY : ON THE NATURE OF MAN. By Morton Levitt. New York : Philosophical Library, 1960.

BASIC THEORY OF PSYCHOANALYSIS. By Robert Waelder. New York : Internat. Univ. Press, 1960.

PSYCHIATRISCHE UND NERVENKLINIK. By K. Kollé. Stuttgart : Georg Thieme, 1959.

PHYSIOLOGICAL TREATMENT

JOSEPH WORTIS, M.D.¹

With over a thousand pertinent papers this past year, and a flood of new products from the companies, it has been harder than ever to do justice to the task of an annual review. A new international journal, *Psychopharmacologia*, has set a high standard in its first issues. Several useful reviews in the field of psychopharmacology are listed in our bibliography(1-7). Reference should be made to some thoughtful discussions of the management of depressions(8-10), and to the large scale pooled data on drug treatments from the VA hospitals(11).

WHICH DRUGS TO USE ?

In spite of the endless chain of patentable phenothiazine derivatives and variants brought into the market, Hurst(7) does not believe that any of these can usefully replace chlorpromazine, and suggests that in those rare cases where jaundice or agranulocytosis has occurred, fluopromazine could be substituted. The combined experience of 37 VA hospitals also tends to establish the value of chlorpromazine(11). For the management of depressions, imipramine (Tofranil) has won wide support(12-15) and phenelzine (Nardil) approaches it in efficacy(16-18). Together they appear to have practically superseded iproniazid (Marsilid), whose toxicity has proved disturbing (19-20), and drastically reduced the use of EST, which in spite of its crudity still is a quick and sure method for the relief of depressions.

Our use of the newer drugs is still mostly empirical; data from small groups of patients with or without double-blind experimental design are reported with monotonous frequency, while careful first-hand clinical observation is being neglected. Astrup(21) attempts a rational analysis of drug action by reflexologic studies, and concludes that the present range of efficacy of anti-schizophrenic drugs is mainly in the broad category of sedation of subcortical ac-

tivity. "The greater the general impairment of nervous activity, and the more pronounced the dissociative phenomena are, the poorer are the therapeutic effects of ataraxic drugs." Deniker(22) believes that the extreme end product of a drug's action can help us understand its value. Thus chlorpromazine or levomepromazine tend to induce akinesia and bradykinesia, while phenothiazine sulfamide or prochlorperazine induce psychomotor excitement. For this reason the former are used to relieve excitement or hallucinations, while the latter are indicated for withdrawn and passive patients. For perhaps similar reasons Tofranil, an excitant agent, has also been found useful in the management of withdrawn schizophrenic patients(23).

TOXICITY OF PSYCHOPHARMACA

Aside from the relief of target symptoms, toxicity, though minimized by some drug sponsors, remains a basic concern in the selection of new drugs. It should also be remembered that long-term data on chronic toxicity accumulate slowly. In a series of 29 patients treated with Marsilid, Pare(24) found abnormally high serum glutamic-oxaloacetic transaminase values in 9 cases, which returned to normal after the drug was withdrawn. Similar changes, in a smaller number of cases, have been reported with Nardil(25). Though Rees and Benaim(19) concede the value of Marsilid in depression, a full consideration of its toxicity leads them to conclude its use is no longer justified. The phenothiazine agranulocytosis rate has been estimated at about 1:700, though mild leukopenic reactions are quite common(26). Denzel(27) reports that in 14 out of 50 cases treated with ataractic drugs, spinal fluid protein values above 45 mg. were found, while 11 cases showed abnormal gold curves. Sobel(28) reports, or has reason to suspect, fetal damage when pregnant mothers are treated with insulin shock or reserpine, while chlorpromazine can cause respiratory distress in the newborn and may increase the incidence of both

¹ State University of New York Downstate Medical Center, and Jewish Hospital of Brooklyn, Brooklyn 38, N. Y.

antepartum bleeding and prematurity. Roux (29) has induced a very high incidence of fetal death or malformation in mice and rats after prochlorperazine administration. Though its significance can be questioned, abnormal cephalin flocculation tests have been found in 5% of the patients treated with trifluoperazine (30), and have also been found in treatment with chlorpromazine, perphenazine and phenelzine (31).

From another point of view the drowsiness, hypotension, motility changes and even the euphoria induced by some drugs can create legal problems involving traffic offenses (32), for example, especially since chlorpromazine mixes poorly with alcohol (33). Children appear to be especially susceptible to marked motor side-effects from tranquilizers (34-36), and a peculiar susceptibility to heat-stroke among adolescents under chlorpromazine is described (37). In an older population an increased tendency to both injury and illness has been reported (38). In addition to the complications and side-effects mentioned in previous reviews, hairy tongue is encountered in patients on chlorpromazine and mepazine (39). Harnkoff and Heller report memory difficulties in the course of otherwise successful treatment with MAO inhibitors (40). Ciezlak (41) enumerates the extraordinarily varied and occasionally dangerous complications encountered in reserpine treatment; Habel (42) declares that the dangers of its chronic use are still unknown, though 15,000,000 tablets a month are being dispensed in Germany.

KEFAUVER AND THE DRUG PROBLEM

The investigatory activity of Senator Kefauver's committee has pointed up some practices and abuses in the drug industry that are of interest to psychiatrists (43). Intense competition among companies leads not only to valuable discoveries of new products, but also to a confusing and superfluous variety of drugs, which in turn entails an enormous promotional activity that is bound to exaggerate the positive and minimize the negative features of a product. This promotional activity has reached the point where the industry expends \$5000 per doctor per year on the effort, with the burden of expense borne by the public. Thus it

is that one company wholesales reserpine at \$39.50 per 1000 tablets under its trade name, but sells the identical product under its generic name to the government for 60 cents per 1000. The Food and Drug Administration is inadequately staffed and budgeted to maintain necessary safeguards and surveillance, but the busy practitioner is, on the other hand, seldom in a position to sift the details of evidence, often contradictory, to allow him to appraise the drugs. The following brief notes on some drugs are mere suggestions of what the literature contains.

NEW DRUGS

The unique taming effect of chlordiazepoxide on vicious agitated monkeys, dingo dogs and wild animals, stimulated the clinical trials that produced Librium (44-46), which markedly reduces the tension, anxiety and agitation of neurotics, and is said to be very effective in chronic schizophrenia. The side-effects of drowsiness, fatigue and ataxia are infrequent, mild and reversible (47). Two other new sedative drugs related to the phenothiazines are thioxanthene (Taractan) a broad spectrum drug with marked hypotensive action (48-51), and fluphenazine (Prolixin), a trifluoromethyl homologue of perphenazine, possessing extraordinary potency (52, 53).

Some 40 other new products are described in the literature, but usually with little claim to attention. Some are non-toxic and ineffective, others are too toxic, and still others are without unique properties to recommend them. To mention only a few: chlorprothixine (54) acts like a phenothiazine, but is said to be non-toxic; L.I.S813 (Clarmil in France) is a phenyl boric acid derivative of no value in psychoses, but with marked sedative effect in neuroses, anxiety and reactive states (55); I.N.-461, benzlindolyethylpyridine, is a non-soporific sedative (56); aminophenylpyridone (57, 58) (Dornwal) and valmethamide (59) (Axiquel) are supposed to relieve anxiety, etc.; phenylpyrrolidinopentane (Katovit in Europe) increases resistance to dysfunction under stress (60); thalidomide is a safe, non-toxic, non-hypnotic sedative (61); cyclopentimine (62) is a well tolerated anti-anxiety, anti-psychosis agent; recent issues

of this *Journal* contain several reports on other new drugs.

Captodiamine (Suvren or Covatin) is described as a non-hypnotic stabilizer that relieves both agitation and depression(63); two new stimulating agents are 5-phenylpseudohydantoin (Tradon), said to be indicated in mild neurasthenic states only (64), and a new analeptic drug, ANP235, sponsored by Delay and his group(65), is supposedly of special value in psychic changes following organic insults. Hypericin is a fluorescent substance derived from *Hypericum perforatum* that is said to induce marked improvement in most mild or moderately depressed patients(66).

Of special interest is a recent report by Bucci and Saunders(67) on the use of procaine, a most interesting drug with a long history, generally well tolerated and with relatively few dangers. Among other enzymatic effects, it is a MAO inhibitor, capable of relieving both depression and schizophrenic symptoms. It is reported to have a most helpful effect on a group of patients resistant to all other current therapies, enhancing vigor, reducing fatigue, and strikingly reducing blood pressure in hypertensive cases.

FAMILIAR DRUGS

Trifluoperazine (Stelazine) can now be regarded as a well established drug, potent in handling many schizophrenic symptoms, useful in allaying anxiety in neurotics, but with distressing and sometimes dangerous side-effects(68-72). Cahan(73) found it of limited value and of considerable toxicity in an elderly female population. Levopromazine (Nozinan in France) is widely used on the Continent in psychoneuroses, agitated and depressed states, and is well tolerated by the aged(74, 75). Promazine (Sparine), actually the oldest of the ataraxics in common use in this country, is useful for rapid sedation in acute psychoses, but can also be quite toxic, especially for the aged; in moderate dosage, however, it is often better tolerated than chlorpromazine(76-79). Another useful alternative to chlorpromazine is prochlorperazine (Compazine), especially effective in manic and acute delirious states(80-82). Perphenazine (Trilafon) is still widely used(83), thiori-

dazine (Mellaril) is highly regarded(84-86), but mectazine (Pacatal) in a double blind study(87) was much inferior to chlorpromazine for schizophrenia (and produced one case of agranulocytosis); in another study(88) with anxiety states it was less useful than a barbiturate, "and costs 10 times as much."

Fluphenazine (Prolixin) is highly potent in relieving hallucinations and delusions in chronic schizophrenia, but at the cost of so many side-effects its value is doubtful(89). With similar material trifluopromazine (Vesprin) produced good results with fewer side-effects(90). Reserpine(91-93) is still found effective in some schizophrenic cases where phenothiazines have failed.

Haloperidol has been most favorably described by workers in several European countries. Delay and his associates(94) regard it as markedly effective in mania and acute delirium, and satisfactory in acute and chronic, especially paranoid, schizophrenia. It is of relatively little value in depression and hebephrenia. Though quite safe, it induces extrapyramidal motor symptoms in most patients, and sometimes sudden and alarming excitement; special caution is required with the aged(95-101).

Interest is still maintained in azacyclonol (Frenquel) for its almost specific anti-hallucinatory effect(100). Lithium(103-105) is highly effective in aborting manic states. Its chief danger, injury to kidney tubules, can be avoided by cautious dosage and a high sodium intake to promote its elimination. The water-soluble steroid hydroxydion (106-108) is a safe and effective agent for brief narcosis or to promote relaxation for psychotherapy.

Among antidepressants Tofrânîl(109-114) holds first place. In spite of the dangers of agranulocytosis, hypomanic reactions, convulsions and confusion, its good results in psychotic depression are comparable to EST (but not quite equal to it); it is of little value in the mild depressions often seen in office practice(115). In resistant cases Lehmann(116) recommends combination with an induced febrile reaction. Nialamide (117) (Niamid) and phenelzine(118) (Nardil), both less toxic than Marsilid, will sometimes work when Tofrânîl has failed, though Nardil can induce liver disturbances,

headaches, insomnia, edema, excitement and hypotension. Isocarboxazid (Marplan) another MAO inhibitor, has also proven to be an active and usually well tolerated antidepressant, though still too new to be adequately rated (119, 120).

PSYCHOSURGERY

WALTER FREEMAN, M.D., Ph.D.¹

An improvement rate of 96% in leucotomized patients is more likely to cause raised eyebrows than raised hopes. Nevertheless, the report by Thorpe(16), who has been following his patients assiduously, shows that 87 of 97 survivors of operation were discharged home. Most of the patients were over 50 years of age. These results were obtained by electrocoagulation of the ventro-medial quadrants of the frontal lobes. There were no serious personality defects. The author concludes that on the basis of a 2-7 year follow-up a 95% total improvement rate "may be regarded as the best one could hope to obtain with any neurological procedure in institutional cases."

While no other authors have reported such extraordinary recovery rates, a Canadian group(8), comparing bilateral and bi-medial incisions in matched patients, found in their social evaluation that 80% of non-schizophrenics were out of the hospital. Duration of hospitalization was particularly important, the discharge rate being 75% in those hospitalized less than a year, 55% in the 1-3 year group and 35% in those hospitalized for 4 or more years. Bischoff(4) and Rémy(14) found the major prefrontal operation more effective in schizophrenics.

Lesse(9, 10) speaks of "decompression of anxiety" as a necessary preliminary to progress in therapy of other clinical symp-

toms. This was most graphically demonstrated in patients undergoing lobotomy under local anesthesia. Of 34 patients 29 demonstrated a definite decrease in anxiety during or just minutes following lobotomy. "We found that the clinical psychiatric symptoms (*i.e.*, phobias, hypochondrical reaction, *etc.*) did not begin to fade until the affectual component of anxiety was first significantly ameliorated." McReynolds and Weide(11) assert that the only psychological measure of great predictive importance is concept evaluation in the Rorschach test. This was interpreted as related to the decrease in anxiety following lobotomy.

Barahona Fernandes(2), reviewing the results of Egas Moniz, states: "To act by means of surgery upon diseases purely functional and even psychogenic such as neurosis, was one of the greatest ventures of the Master. It made psychologists shudder and psychotherapists angry. But the fact was there, undeniable, and the future has confirmed it." Referring to excellent results in superior individuals such as a priest, a physician and a university student he admits that there are, in other cases, relapses, further progress of the underlying disease and persistent defects. "Leucotomy may accentuate or quicken the deficit of personality begun by the schizophrenic 'morbus.' It is a fire that extinguishes itself and shows the damage done. The delusions disappear

¹ 91 Main St., Los Altos, Calif.

but the defect remains, sometimes even more evident. The operation gets the blame for things that belong to the illness . . .

"Leucotomy creates new conditions of accessibility and reaction of the patient (syntonization favoring the vital transference) which should be adequately used for the aimed purpose—diminution of suffering and adaptation to reality."

In a brilliant discussion of "Where Vital Things Happen" Grey Walter(7) shows how emotionally disturbed individuals may respond inappropriately in test situations where simple responses would avoid penalties. He speaks of the "puppet theatre of our laboratory" where a "tragic breakdown" of the mechanism [is manifested by] the total failure of two patients to control by the twitch of a muscle a situation that could be mastered in a few attempts by the humblest experimental animal. Leucotomy corrects this inappropriate response.

Angyán, Huszár and Nyiró(1) studied an obsessive patient by conditioned reflex analysis before and after successful lobotomy. "In place of the typical reflex formation and overwhelming rigid blocking and abstraction in the second signal system there appeared a labile but less differentiating status with concrete formulations." Barber (3) believes that relief of pain by leucotomy is due to the alleviation of worry and concern, a state that can be accomplished in some other patients by opiates, placebos and hypnosis. The common behavioral matrix is a mitigated readiness to respond to stimulation.

The curious compartmentalized attitude toward lobotomy crops up in Brizzi's(5) report. In one paragraph: "All depressive psychotics recovered, while 70% of the control group had to be readmitted." In another

paragraph: "In principle the author does not believe that a cure was ever attained in any of his patients."

Many lobotomized patients deny having been operated upon. Paganini and Zlotlow (13) found that denial was a continuation of the defense mechanism employed by schizophrenics previous to lobotomy.

CHILD PSYCHIATRY: MENTAL DEFICIENCY 1960

LEON EISENBERG, M.D.¹

Addresses, without number, to community groups on mental hygiene must be reckoned as one of the not inconsiderable occupational hazards of the child psychiatrist. Even if we set aside the problems arising from the

cumulative impact of successive nights away from home on our psychic economy (and that of our children), there remain quite fundamental questions as to what we should attempt to teach and as to whether lectures, group discussions, television programs and the like are at all effective in changing the

¹ 2610 Whitney Ave., Baltimore, Md.

behavior we set out to modify. At an Assembly jointly sponsored in 1958 by the APA and the N.A.M.H., whose proceedings have just appeared(1), issues of content and method in mental health education were subjected to a penetrating, sophisticated, and long-needed critique. The monograph makes abundantly clear the urgency of re-examining goals, weighing the evidence for the aphorisms so readily dispensed, and attending to the very real possibility that "education for mental health," if not carefully scrutinized, may have unintended negative consequences. When we urge better care for the mentally ill and public support for the recruitment and training of mental health personnel, we stand on solid ground. Beyond this point (which is to say, beyond our own area of clinical expertness), the footing is at best precarious, even for the angels among us. What constitutes positive mental health, how it should be taught and whether it can be taught at all remain questions of dispute among serious workers in the field. This caveat to the seller is not a call for a moratorium on public education for mental hygiene; it is an appeal for a more searching examination of conventional beliefs and for studies to evaluate the results of educational efforts.

Few of us read Russian; in consequence, the work of our Soviet colleagues has remained largely unknown in this country. A recent volume, distributed to medical libraries by the Public Health Service, provides in English translation a series of "representative" publications from the Russian neuropsychiatric literature(2). Papers with specific reference to child psychiatry include studies in the conditional responses of neonates(3-6), constitutional "types"(7-8), verbal behavior (the second signalling systems in Pavlovian terminology)(9-13), and performance characteristics (will) (14). The notational and conceptual framework is Pavlovian; the experimental approach focuses on intensive study of a limited number of subjects rather than a large statistically analyzed series. The practical emphasis is notable throughout, with the implications for child rearing and pedagogy spelled out by the investigator. To judge from the bibliographic citations, there are a wealth of studies in areas, such as the neonatal period,

which have been far less extensively explored in this country. Novlyanskaya's paper on anorexia nervosa(15) makes heartening reading in view of the common assumption on these shores that the Soviet psychiatrist neglects motivational and psychotherapeutic considerations; with transposition of terminology, the findings harmonize remarkably well with the clinical themes evident in American studies of this disorder(16).

A very welcome addition to periodicals is the new and excellent British *Journal of Child Psychology and Psychiatry* under the aegis of the distinguished Emanuel Miller, who contributes a notable "discourse on method" to its maiden issue(17). Clarke and Clarke(18) review their own and related studies in maternal deprivation; without minimizing the importance of social measures to prevent this condition, they emphasize the positive gains that remedial measures can offer neglected children and conclude that the severity and permanence of the effects of the milder (and more common) types of deprivation have been overestimated in the earlier reports in the literature. That it is not the physical separation and institutionalization *alone* but rather that plus the experience of being rejected and remaining unwanted that leads to emotional difficulties and character defects is indicated by Kellmer Pringle and Bossio's study(19) on deprivation. Does manic depressive psychosis exist in childhood? This much-vexed question has been examined by Anthony and Scott in a scholarly paper(20) which reviews the available literature, offers a set of definitive criteria for the diagnosis, and describes a rather classical case with onset at the age of 12: this treatise should become required reading. Companion papers from the Maudsley by Hersov(21, 22) are significant additions to the literature on school phobia. In the first, 50 phobic, 50 truant and 50 normal cases are contrasted, with clear evidence for the psychoneurotic constellations in the phobic children and their families(21). The second examines the therapeutic outcome for 29 inpatients and 21 outpatients(22). Thirty-four were enabled to return to school, 12 were failures and 4 experienced relapses after initial success; somewhat at variance with findings in this country(23, 24), no significant correlation

could be established between outcome and age. Creak and Ini's (25) study of the families of 102 psychotic children emphasizes the variety of manifest attitudes displayed by these parents, with 13 of the mothers described as warm and 59 as average in maternal characteristics; they conclude: "This study hardly supports the view that parental personalities and child-rearing attitudes as seen in our sample are a principal cause of childhood psychosis." Yet in the same year Kaufman and his associates (26) have proposed the thesis that a psychotic core is found in the parents of schizophrenic children as they study them clinically. How are these antithetical positions to be rationalized? Differences in methodology are clearly important; the former study proceeded by clinical interview in the course of diagnostic examinations, the latter by long-term psychoanalytic investigation. There may very well be important differences in the composition of the groups of "psychotic" children studied; I have elsewhere commented on the heterogeneity of the conditions clinically categorized as childhood schizophrenia (27). The problem, however, goes beyond these matters to basic conceptualizations and interpretations as to the kind of evidence that is considered admissible to court. For the moment, the clash of opinion must remain irreconcilable.

It has long been recognized that the public school system with its almost total sampling of the child population and its captive audience offers an unparalleled opportunity for investigations of epidemiology and prevention; only recently have large scale efforts to capitalize on this situation been undertaken. A recent issue of the *Journal of Social Issues* (28) reports a number of important studies. The St. Louis studies (29, 30) indicate that teachers' judgments and ratings of academic progress succeed in identifying disturbed children, although social class is clearly a significant variable in influencing both teachers' and mothers' ratings of children (31). Bower's valuable monograph (32) concurs in the important conclusion that teachers are effective case finders when a variety of indices including sociograms and rating scales are made available to them. (The methods developed by Bower represent a significant contribution in them-

selves). A somewhat discordant finding has been reported by Goldfarb (33). In the Baltimore study, major discrepancies were noted between teachers' and clinicians' judgments on the same group of children; although both sets of raters reported similar percentages of children as in need of treatment, in only a third of the cases were they describing the same children. It should be noted that there were important differences in method between the former studies and the latter; generalizations from data must be phrased in terms of the questions asked and the methods used at this stage of imperfection in our techniques.

MENTAL DEFICIENCY

The past ten years have seen a revival of interest in the care of the defective that invites comparison with the spurt of progress in the early years of the 19th century when the first systematic medical studies were undertaken. This era may differ somewhat in the extent of the impetus supplied by scientific technology which has made possible the specification of enzymatic and chromosomal aberrations. But it shares the humanistic motivations of the earlier period. Then it was the philosophy of the enlightenment and the doctrine of human perfectability that gave courage to those who attempted to teach the deaf, the blind, and the imbecile; now it is the democratic belief in the dignity of the individual and the inspired crusade of parent groups through the N.A.R.C. that leads us to reevaluate practices which had become static and rigid. The history of what has happened can provide clarifying perspective to what is happening.

Leo Kanner, a contemporary pioneer in reintroducing mental deficiency as an area of legitimate concern for psychiatry, has embarked on a series of scholarly studies to be embraced ultimately in a promised monograph which should provide a definitive history of the field. The first two fruits of this endeavor have appeared in print (34, 35). Johann Jakob Guggenbuhl founded the Abendberg, a Swiss institution for cretins, that was to be the inspiration for schools for defectives throughout Europe and America (34). To enter upon so difficult an enterprise called for single-minded dedication

and an evangelical spirit; the enthusiastic reception that greeted his efforts led Guggenbuhl to devote himself to spreading the new gospel to the neglect of his responsibility to his own charges. Just at the point when his career was at the Zenith, his clinical accomplishments and his own integrity were challenged; his Abendberg was closed by an official commission—but not before it had sparked world-wide efforts to educate the retarded. A paper on Itard, Seguin, and Howe(35) serves to remind us once again of the role of the physician as a crusader for human betterment as well as a scientist. These essays repay thoughtful reading; perhaps they can recall us to a function that all too few of us have been willing to undertake on behalf of the defective. They provide a noteworthy foundation for the Adolf Meyer Lecture of Sir Aubrey Lewis(36), an insightful discourse on the social and scientific aspects of contemporary attitudes toward mental defect.

Exemplary of the new psychological research into mental deficiency in England are three studies by Lyle (in a new and welcome Journal) upon the effect of an institutional environment on the verbal development of severe defectives(37-39). The performance of mongol and non-mongol defectives in an institution and in a day school have been contrasted. Whereas the non-verbal "mental age" of all groups was similar, the verbal scores for the day school groups, both mongol and non-mongol, were shown to be superior. Inspection of the mongol data indicated that these children had less verbal skills than the non-mongol defectives and that they suffered *more* retardation in the institutional environment than did the non-mongols. When an experimental group of 16 previously institutionalized defectives were transferred to a residential family unit and nursery program with a higher staff/patient ratio, they showed significant gains in intellectual development in comparison with a control institutional population. This stimulating effect of an enriched environment has been shown in other English studies(40, 41) which reinstate the findings of some pioneer American investigations of the '30s(42). A useful bibliography of current research in the United States may be found in

a pamphlet issued by the Children's Bureau (43).

What factors influence the decision to institutionalize the defective? Parental rejection, I.Q., delinquent behavior, dearth of community services? In place of the clinical impressions we have had to rely upon in the past in order to essay an answer to this question, we now have a solid body of data provided by an excellent monograph on this subject by Gerhart Saenger(44). Personal and familial characteristics of retarded N. Y. city residents were contrasted for those in and those out of institutions. The finding that parental rejection is *not* a major factor is in itself a significant contribution that may finally lay the ghost of a widely perpetuated myth that makes even more difficult the plight of parents who must face this eventuality. The decision to institutionalize, the New York study demonstrates, relates to such considerations as: the severity of the retardation, low economic status and minority group membership, behavior difficulty (especially sexual acts), broken homes and parental inadequacy. Deficiency in community services is a determinant in the case of the severely but not the moderately retarded, since the latter are likely to be institutionalized for reasons other than the retardation *per se*. Collateral findings include the identification of Puerto Rican children committed as defective on the basis of incorrectly interpreted test findings that made no allowance for language difficulties!

Public policy toward mental deficiency continues to be influenced by deeply imbedded social prejudices and to reflect antiquated medical principles. Our responsibility as physicians clearly extends to our role as citizens. Much remains to be learned but surely it is inexcusable that what we now know is not being fully used.

OCCUPATIONAL PSYCHIATRY¹

RALPH T. COLLINS, M.D., MEd.Sc.D.²

Smith(1) in an article entitled "The Promotion of Health," points out that an increasing number of people are becoming exposed to an industrial environment and industrial medicine has to play more of a role in promoting the health of the nation. In industry today, injury, illness, frustration, and unhappiness bring suffering to employees and their families and problems to

management. Some of the circumstances which give rise to these mishaps could have been anticipated and avoided. Their prevention is the concern of industrial medicine, which draws attention to the existence of such circumstances and encourages action to obviate them. In order to deal with the multiplicity of problems, he feels a team approach is the most efficient.

VOCATIONAL REHABILITATION

Progress continues for the vocational rehabilitation of those persons who have had an emotional upset or a mental illness. Last year the Executive Committee of the President's Committee for the Employment of

¹ Appreciation is due the other members of the Committee on Occupational Psychiatry, APA, and American and foreign correspondents. Special acknowledgment is due to Dr. John Pixley, Department of Psychiatry, University of Cincinnati, School of Medicine for valuable help in the preparation of this article.

² 343 State Street, Rochester 4, N. Y.

the Physically Handicapped passed a resolution to study the problem of incorporating promotional responsibilities for aiding the employment of those persons with histories of emotional or behavior problems into its program, and asked Dr. Ralph T. Collins "to chair a subcommittee of the Medical Committee to make recommendations as to how best to carry out the intent and principles of the Executive Committee's Resolution." This Subcommittee on the Emotionally Restored reported the following decisions to the Executive Committee through its chairman, viz.:

1. The mentally restored and the mentally retarded should be included in the philosophy and the program of the President's Committee. The emphasis might well be placed on the mentally restored as these, by and large, are more employable, educable, and trainable. Also, there are many agencies, voluntary and others, who are working with the mentally retarded up to the age of 18.

2. There is discrimination against the mentally restored relative to employment and reemployment. This is a manpower problem and a humane one as well.

3. The gathering of data pertaining to this subject, the constant suggesting to Governors' Committees and grassroots local Mayors' Committees that attention be paid to this subject, and the "cautious approach" and the "deliberate speed" attitude, are recommended.

4. Suitable articles regarding this subject might be published in *Performance* and NEPH pamphlets. We agree that there is much education to be done at all levels of management, among the work force, within unions and the medical profession, including, of course, the psychiatrists and the mental hospitals.

5. We agreed that more effective communication should be developed between the psychiatrist, the plant physician, and the supervisors, all working toward the welfare and benefit of the employee and eventually the industry.

6. We agreed that although each case must always be individualized on a face-to-face and fact-to-fact basis, and that motivation of each mentally restored employee must be considered, this is of no avail un-

less top management has decided that the handicapped shall be employed and that all levels of management be so appraised and educated to the belief that "it really pays to hire the handicapped."

7. We agreed that the President's Committee can aid the mentally restored and the mentally retarded in its informational, educational, and promotional programs. We recommend that the President's Committee include these workers in its overall program.

The Executive Committee accepted the report and agreed to incorporate the mentally restored and the mentally retarded into its promotional program. Dr. Collins was asked to become a member of the Executive Committee and to chair a permanent Mental Health Committee. This committee would have equal standing with other standing committees of the President's Committee. Major General Melvin K. Maas, Chairman of the President's Committee for the Employment of the Physically Handicapped has issued invitations to individuals in many fields of endeavor to become members of this committee. The first meeting of this committee was held at noon at the Willard Hotel, Washington, D. C. on Friday, November 18, 1960. The staff of the President's Committee has been expanded and work has already begun for this purpose.

During this past year, there has been an increase in programs devoted to the employment and reemployment of those persons who have had a mental illness. These have been sponsored by voluntary mental health agencies, governmental agencies and hospitals and Governor's and Mayor's Committees on the Employment of the Physically Handicapped. It is to be noted that the word physically has been dropped from the official title of a few of the Governor's Committees.

Simon(2) broadens the definition of psychiatric rehabilitation to include the therapeutic use of the self. This relationship is designed to meet the patient's needs enabling him to communicate well with others and in general increasing his participation in the social group. Rehabilitation includes "every aspect of the treatment of the whole person." It is depicted as including 6 areas of living (psychological, vocational, family,

socio-recreational, educational and community). Simon feels the community physician will play a very important role in fostering a continuum from mental hospital-integrated living and the industrial physician "can play a very crucial role in psychiatric rehabilitation."

Hewitt(3) points out that the tradition of state supported mental illness in large institutions is now being replaced, to a large part, by small short term outpatient clinics, day and night hospital facilities, half way houses and the like. He also speaks favorably of the increasing role played by vocational rehabilitation programs. As trends: the industries and unions are now often underwriting the cost of mental illness for their workers and in this state of change, he makes a plea for coordination in planning future mental health facilities.

EDUCATION AND TRAINING

Increased educational and training opportunities are now available in residency programs in the United States. Among these elective experiences are rotation through the occupational psychiatry program at the Department of Psychiatry of the University of Cincinnati and at the University of Minnesota. Both programs are stimulating active interest of eligible third year residents. Cincinnati has started its occupational psychiatry training with two residents currently participating on a half-time basis; Minnesota with one for one-half day per week. For the fifth year at the Menninger School of Psychiatry second year residents are offered a 12 session seminar in occupational psychiatry; 14 residents are currently enrolled. The Cornell University two-year fellowship program continues active for post-residency training.

For physicians in occupational medicine, week-long annual seminars are conducted by the Division of Industrial Mental Health of the Menninger Foundation. One hundred physicians have attended thus far. Psychiatry is included in many training programs in occupational medicine such as those at the University of Cincinnati, at New York University, and in the preventive medicine courses of the American College of Physicians. Psychiatry training for physicians in

single companies appears also to be an increasing trend.

1960 also demonstrated an increase in training programs for executives and management personnel in understanding emotional problems in the work situation. Such courses are sponsored by academic, community and business organizations. More than one hundred such programs were conducted. A few illustrative ones were those of the Conference on Mental Health in Industry at Allenberry, Pennsylvania, those sponsored by Temple University Department of Psychiatry, the Division of Industrial Mental Health of the Menninger Foundation, the University of Arizona, Arizona State University, the University of Colorado, the Phoenix Institute of Neurology and Psychiatry, the Connecticut Mutual Life Insurance Company, and many local, state and national mental health societies.

NEW APA PUBLICATIONS

In 1960 the APA Committee published a pamphlet *Troubled People on the Job* designed for those in supervision and management in industry. Sales exceeded 22,000 copies during the year. The committee also began publication of a quarterly *Newsletter* summarizing current activities in the field both in this country and abroad.

EXECUTIVES AND MENTAL HEALTH

Habbe(4) reports on some 200 executives from 80 corporations who, in discussing the aims of business, came to the conclusion that total health (mental and physical) of the corporation was very important. The conclusion that the cost of neglecting mental health was probably about four times that of caring for it adequately was expressed. Resolutions were passed to attempt to utilize more psychiatric manpower toward this end, and relieve the load which was falling on relatively few.

Hayes and Hayworth(5) in an article entitled "Psychiatric Breakdown in Higher Executives" state in substance that of the factors commonly supposed to be important in executives' breakdowns only work was doubtfully ascribed significance, while fatigue as such did not emerge as an important part of the stress involved. No

special type of psychiatric illness seemed to occur in the executive group and such significant differences as are to be seen reflect, if anything, the "better" type of personality possessed by the executive group (as compared to the worker control group). The authors plan to follow up with a more definitive study on the above model.

An article entitled "The Health of the Executive" (6) which appeared in the transactions of the association of industrial medical officers, examines critically the hypothesis that today's executives are suffering unduly from 3 categories of disease (cardiovascular, psychosomatic and psychoneurotic) and finds little clinical evidence to support that they are. The question is raised as to the amount of stress being placed on the second tier of management and if actually this is not the most logical population to suspect. Here also, there is no definitive evidence. The suggestion is made that a critical evaluation of 20th century living, including job evaluation may be productive.

Robinson (7) in an article entitled "Stress" enlarges Selye's definition of stress to "anything which threatens the biological integrity directly (physical or chemical) or indirectly (symbolic meaning)." It therefore denotes combined subjective and objective physiological and psychological reactions which in certain conditions may become pathological. The objective assessment of stress is not adequate for indicating early manifestations; we must rely on clinical judgment and subjective experiences. He then makes a strong point for some of the beneficial aspects of stress and debunks the implication that stress is "bad." He discusses stress diseases, pointing out that the starting point is a "threat to security" and followed by a chain reaction with organic and psychological feedbacks. In concluding, the author warns us against being too quick to treat only the organic aspects of stress diseases.

AUTOMATION

In the *Bulletin of Hygiene*, April, 1960 (8) there is a report to a study group of the mental health problems of automation. This study, using as a definition for automation, "the coming together of several relatively independent streams of technical

progress" outlines 3 distinct fields: 1. Highly developed mechanization; 2. Control of machines by machines; 3. Development of electronic digital computers. The 3rd field is singled out as being to mental health as important as the industrial revolution was in upsetting the status quo. People live and adapt within groups, and threat of change may produce reactions which are as real as if actual changes have occurred. The two resulting problems, actual change, and anticipation of change must be taken into consideration and techniques to handle them smoothly must be evolved if we are to maintain efficiency and worker health. There is a need for more research into the adaptation of the individual, the family, and the community to automation.

INDUSTRIAL ACCIDENTS

Deverell (9) briefly gives some historical background, then discusses various theories. (a) Law of Poisson: Not felt to be accurate, even though certain individuals do exhibit accident proneness, this would not eliminate accidents. (b) Heinrich's pyramid and law of chance. The author utilizes this theory as important in accident prevention. (c) Accident causation: Felt to be about 75/25 with management at 25%. This indicated that the employee must be motivated for safety. Under the heading of human failing accidents, the author feels the main failure is management's; by not properly training, using propaganda or incentives effectively or making employees obey self discipline they are responsible for this category of problems.

He then discusses environment and personal factors, pointing out men work as they live; that physical conditions do affect accident rate and that if proper supervisory levels are maintained size of factory has nothing to do with number of accidents. Research into fatigue and accidents is inconclusive and absences following accidents are individually determined. In this respect, a limit setting homogeneous group can be effective however.

FOREIGN CORRESPONDENCE

Dr. van Alphen de Veer has suggested that the following publications should be

included in this review of occupational psychiatry :

1. H. R. Wijngaarden : The influence of work on mental health. (Maandblad v. d. Geestelijke Volksgezondheid nr. 15.)

2. Dr. J. J. A. Vollebergh : Human Freedom in an organised industry. (Maandblad v. d. Geestelijke Volksgezondheid nr. 15.)

3. Dr. P. J. Willems : The adaptation of work to men. (Maandblad v. d. Geestelijke Volksgezondheid nr. 15.)

4. Dr. G. J. Fortuin : Psychological aspects of the adaptation of work to the worker. (Maandblad v. d. Geestelijke Volksgezondheid nr. 15.)

5. A. H. Hutte : Design of a worksociaty in the Netherlands. (Mens en Onderneming nr. 13 1959 en nr. 14 1960.)

6. Co-operation between industrial doctor and industrial psychologist. A symposium. (Tijdschrift voor Sociale Geneeskunde, Jaargang 38 nr. 22.)

Dr. van Alphen de Veer read a paper entitled "Mental Health in Industry" at the 13th annual meeting of the World Federation of Mental Health at Edinburgh, Scotland in August, 1960. In the opening remarks of this paper he made the following points :

Mental health means : (a) full development of human abilities ; (b) growth to emotional maturity ; avoidance of neurotic tensions ; (c) ability to handle relationships with individuals and groups in accordance with existing cultural patterns(10).

Here is a definition given by Prof. Koekebakker in 1952 on the Seminar of the W.H.O. at Leiden, that will be useful to us in our study of the mental health situation in industry. Speculation about the full development of human abilities and the advance to emotional maturity immediately raises the question as to what extent, in general, work in industry offers an opportunity for these things. Or, on the other hand, does work in industry constitute an obstacle to them ? The question cannot really be formulated in such simple terms, for technological development and the development of the human personality are two entities with different dimensions. Nevertheless, to create as favourable a climate as possible for the worker, and to organize his work in such a way as to promote mental health,

these constitute a task of the highest importance in the field of mental hygiene. Again, how far can we hope to succeed in these endeavours and what is the correct way of approaching the problems involved ? Here, it is clear, we are standing on the verge of an extensive territory that has already been reconnoitred from all sides. Much has been done to investigate mental health in industry, and a great deal has been written about the subject, and this makes it difficult to give a succinct review of the present position. Still, it seems to be high time that the matter was raised once again.

RESEARCH

The Industrial Mental Health Project of the University of Cincinnati, College of Medicine has completed its first phase of study, a follow-up of employees who had been seen in industrial psychiatric conferences over a period of ten years. The most striking finding statistically was the highly positive correlation between measures of improvement and the degree to which recommendations of the conference had been carried out. The team is now collecting data on problem cases (absenteeism, accidents, interpersonal difficulties and frequent dispensary visitors) and on controls, with split half comparison, of the sequels following psychiatric recommendation, with the sequels following psychological testing and collecting data on problems without mental health interview(11).

Accidents are the concern of a report by Collins(12) in which it is noted that accidents showed a positive correlation between ethnic group, age (highest in 26-35 group, lowest in over 56 group), day of week (highest on Monday). Modlin(13) reports on patients referred to the Menninger Clinic with a presumptive diagnosis of "traumatic neurosis." Focus is on clinical analysis of the psychological stress factor in the traumatic neurosis syndrome frequently seen following accidents. Two sets of circumstances are identified as operative in initiating the syndrome : 1. The patient-to-be experiences a brief forewarning of impending disaster, or, 2. The accident occurs suddenly, unexpectedly and without forewarning. Leopold and Dillon(14) summar-

ize their findings of 47 cases of whiplash injuries of the neck, pointing out that evaluation of the psychiatric factors is difficult because of the frequency of concomitant cerebral concussion.

The successful placement and adjustment of cardiacs continues to be the concern of industry. Gelfand, *et al.* (15) report findings on 117 cases seen in a Cardiac Work Classification Unit. The unsuccessfully vocationally adjusted group was composed of predominantly obsessive-compulsive personalities. Schedules for collection of data and a method of approach to the problem by a team of specialists are described. Weaver (16) gives an analysis of his experience in the selective placement of cardiacs in a large refinery. The program utilizes the matching of the workers capacities with the physical demands of the job.

SOCIAL PSYCHIATRY

MAX P. PEPPER, M.D., AND F. C. REDLICH, M.D.¹

INTERDISCIPLINARY APPROACH

Interdisciplinary research projects in which psychiatrists work with social scientists seem now to be a well-established and increasingly valued principle of approach to the problems confronting psychiatric theory and practice. Results of such teamwork are illustrated by the reports of the Joint Commission on Mental Illness and Health, comprising several important publications (1, 24, 30, 57). The bulletins issued by the World Federation for Mental Health in conjunction with World Mental Health Year activities (72), and the publications of the World Health Organization (60, 67, 73,

74, 75) exemplify international cooperative endeavors.

MANPOWER STUDIES : THE PROFESSION, ITS INSTITUTIONS, AND THE COMMUNITY

Clearly, the manpower crisis facing psychiatry and the other mental health professions in the more highly industrialized societies has had its great share in stimulating such interdisciplinary research activities. A number of studies suggest the importance attached to manpower considerations in the problems facing psychiatry now and in the foreseeable future (1, 7). Albee, in his study for the Joint Commission, concludes that "we should at this time withdraw some money and manpower from the support of treatment services (with full realization that

¹ From the Department of Psychiatry, Yale University School of Medicine, New Haven 11, Conn.

this means further neglect of already poorly cared for patients) and use the competent manpower and money for research on causes and more effective treatment of mental illness." Patterns and problems concerning recruitment of psychiatric manpower, and associated problems of the medical curriculum at both undergraduate and graduate levels, thus constitute a major area for investigation with the obvious hope that satisfaction of the critical need for rational design and planning of manpower resources will be achieved (28, 36). Corollary to this is the urgency of the need for planning institutions and community services that will more effectively serve needs for psychiatric services. Continuing reports of psychiatric institutions, such as that of a state hospital viewed as a small culture or society (related, to be sure, to the values and organizing principles in the society or dominant culture at large), are thus not only of great potential value for effecting reforms in the particular institution being studied, but also in setting into clearer perspective the problems of over-all professional and social planning (22, 43, 47, 64). The rapid growth and development of the "open door" policy in large mental hospitals, and increasing interest in the elements of a therapeutic community and in such services as psychiatric home-care programs, halfway houses, and other specialized aftercare facilities attempting to cope with the rehabilitation problems of former patients, psychiatric units in general hospitals, community mental hygiene clinics, and special services for particular groups in the population (e.g., the aged, alcoholics, criminal offenders), represent converging patterns of the effects of social psychiatric research efforts, changing exigencies of psychiatric manpower resources, and the increasing awareness of the general public of its mental health problems (8, 9, 25, 32, 38, 41, 59). Another publication of the Joint Commission documents, via the results of a detailed interview schedule administered to a probability sample of the entire American population, "what Americans think of their mental health" (30). This outstanding study reveals that the major national issues, the international situation, the threat of atomic fallout, the housing shortage, crowded highways, etc., appeared to

be an important source of worry to few people whereas everyday personal tribulations with which people are faced (health, families, children, money, job situations) constitute the common concerns of most people. Assuming this information to be valid and reliable, one can only wonder at the social and psychiatric implications in such a seemingly basic unconcern with momentous problems—or the massive denial of them.

TRANSCULTURAL AND CROSSCULTURAL PSYCHIATRY

The contents of the *Transcultural Newsletter* (71) help provide a picture of developments in psychiatry in various cultural settings around the world. Opler's reader (54) in "Culture and Mental Health" also serves as a good bibliographic source to studies in diverse cultures. The reprinting in this volume of classic papers by Wittkower and Fried, Lin, and others, as well as a wide representation of papers published for the first time, offers a sound introduction to this important literature. In the rapidly developing unindustrialized nations, where the need for sanitary reform and adequate nutrition in public health practice far transcends in importance the considerations of mental health resources at present, it is encouraging to witness, nevertheless, an enlightened concern for use of epidemiological studies to plan the orderly development of psychiatric services. One may justly hope that this will help avoid some of the costly errors in the development of psychiatric practice in Western Europe and America during similar periods in their technological growth. The variety of studies accumulating from the four corners of the world is gratifying (5, 6, 12, 20, 21, 33, 34, 35, 42, 58). A classical problem in transcultural psychiatry which continues to be explored is the relationship of migration to mental health (11, 19, 23, 26, 45, 48, 49). The rapid cultural and social changes in many parts of the world associated with population movements, technological developments, former colonies achieving independence, rural-urban migration, etc., constitute a natural "experimental opportunity" for epidemiological investigations. Earlier studies in migration in relationship to mental health

were used in this country to justify restrictive legislation on immigration. Such use of tentative conclusions in the service of discriminatory social legislation would now seem clearly to have been unwarranted (66).

It is well to bear in mind that in the absence of adequate systems of classification and nomenclature, many crosscultural studies tend to be hopeless conglomerations of disparate observations. Without more systematic and standardized methods of reporting results, it seems premature at this point to hope that factors of universal significance in the etiology of mental disorders (non "culture-bound") will be separated out by such studies (13, 67, 73).

EPIDEMIOLOGY AND PSYCHIATRY

The methodology which promises to provide a uniting element in social psychiatric research is that offered by the application of the epidemiological approach (long recognized as the basic tool of preventive medicine) to the study of psychiatric problems.

Several important statements on the general applicability of epidemiological methods and their limitations in psychiatry have appeared during the past year. Two of these are excellent and succinct summaries published under the auspices of the World Health Organization, and another of the volumes in the Joint Commission series also summarizes the progress to date in applying the general principles of the epidemiological method to mental disorders (17, 27, 52, 57, 60, 73). These reports, taken together, represent a basic and indispensable statement in this field and present recommendations pregnant with possibilities for productive research.

It is obviously impossible to review in this brief survey all the recent publications demonstrating the application of epidemiological methods in psychiatric research. We can only cite several to illustrate the catholic nature of these applications. The first volume of one of the most ambitious undertakings to date has now been published, which outlines the general research design and formulates the major hypotheses of this monumental project (44). The succeeding volumes presenting the results obtained in the Nova Scotia study are anxiously awaited

for the wealth of information they will undoubtedly provide in respect to incidence and prevalence of mental disorders in the study population, support for hypotheses concerning the relationship between social disorganization and the occurrence of illness, and pointing the way to further investigations. The other major epidemiologic survey awaiting publication, the "Midtown Manhattan" project of Rennie, Srole, *et al.*, will also undoubtedly add greatly to our existing fund of knowledge in similar dimensions.

Actually, studies utilizing the epidemiological method in psychiatry have been performed for many years. It is to be hoped, however, that the clearer formulation and wider dissemination of the principles of epidemiology among the mental health professions will result in more careful and specific planning of research projects.

Follow-up Studies: For example, follow-up studies in psychiatry (which until just recently have been all too few and far between) represent an ideal opportunity for use of an epidemiological model. The study by the late Dr. Norris of "Mental Illness in London" represents one of the more sophisticated efforts in dealing statistically with a cohort of hospitalized patients (53). This and other studies of follow-up, be they of a specific diagnostic entity or syndrome (2, 39, 46, 61, 62, 65), of specific treatment modalities (14), or other similarities in the group being studied, holds the greatest promise for refining our present notions of the natural history of psychiatric disorders (56, 63). The follow-up study application of epidemiological techniques (as distinguished from the non-longitudinal or cross-sectional survey applications) also should yield important clues concerning etiology. Such studies as those of Wilner, *et al.* (70), in the field of housing in relation to social and health adjustment, are also worthy of particular note.

Innate and Acquired Etiological Factors: Another facet of application of epidemiological methods is demonstrated by studies in genetics and the social structure of small groups, especially the family. An excellent review of the status of knowledge in genetics is given by Böök, in a book edited by Jackson, and in another publication (10,

37). In Jackson's collection are to be found other important statements regarding the etiology of schizophrenia (including his own critical review of the field) from the standpoint of family dynamics, sociology, biochemistry, physiology and psychology.

Work on the families of patients with mental disorders utilizing the index case approach, exemplified by the studies of Lidz and Fleck(37) and others(15, 29, 31, 68), represents still another aspect of epidemiological research. The reader edited by Bell and Vogel provides an excellent selection of writings pertaining to the family (4).

Studies of social factors influencing length of hospitalization(16, 18) and specific events in the life histories of patients(3) illustrate other features of application.

The studies of Pasamanick, *et al.*, regarding such variables as prematurity and seasonal variations in births(40, 55) have recently been discussed and challenged in a provocative critique of their statistical methods and assumptions(69). Aside from the specific points at issue in this particular controversy is the sobering realization that once results have been published as "facts," they tend to assume a peculiar life of their own, becoming divorced from the body and context of the investigation from which they derived.

SOCIAL THEORY AND MEDICAL SOCIOLOGY

Analogous to the interdisciplinary excursions by psychiatrists into the social sciences is the venture of social scientists into the world of medicine and psychiatry. The social scientists' approach to medicine, initially concerned primarily with the field of psychiatry, is rapidly extending to other areas of medicine: its practice, institutional roles, and structures. The importance of this development as a potential in providing feedback of psycho-social information to the medical professions in general can hardly be overestimated.

In the enthusiasm for gathering data which is best exemplified by the ever-widening application of the epidemiological model, it becomes increasingly important not to overlook and relegate to dusty corners the great germinal ideas in classical sociology and psychiatry. Perhaps the danger of

doing so is less in psychiatry, where in a half century's growth of schools of psychoanalytic thought abundant numbers of hypotheses and theories to be tested have emerged in the areas of personality development, etiology of illness, and the relationship of the individual to society. Mills, in presenting and stressing the case for re-studying the classical tradition in sociology (50, 51), has revitalized the contributions of sociological theorists as a legitimate stimulus for creative explorations in social psychiatric research.

CLINICAL NEUROLOGY

WILLIAM H. TIMBERLAKE, M.D.¹

CIRCULATION

Brain injury predisposes to early cerebral strokes(6). An elongated carotid is apt to kink when the head is turned to that side (172). In Carotid Sinus Syndrome, in addition to slowing of the pulse, the intra-arterial pressure falls and with narrowed cerebral vessels may cause focal symptoms(90). An electrocardiogram should be done in all stroke patients to identify any underlying recent myocardial infarct(177).

Occlusion of the internal carotid is confirmed by ophthalmodynamometry, 80 percent of the time(203). A bruit is audible over a stenosed carotid in slightly more than half the patients(166). Compression of the carotid low in the neck causes syncope about this frequently with proved occlusion of the opposite carotid(204). Absence of the carotid pulse in the pharynx is a little more reliable. Diminished carotid pulsation in the neck is least reliable. A bruit is sometimes audible at the base of the neck in vertebral occlusion(166). Nearly half of the patients with carotid occlusion have a partial Horner's sign(89).

Half the patients with basilar artery thrombosis give a clear history of previous ischemic attacks, and circum-oral numbness is often described(4). Large lesions of the tegmentum between the third and seventh nerves cause coma ; lesser lesions may cause akinetic mutism(41).

Persistent coma and severe underlying cardiovascular disease worsen the prognosis in a stroke(89). However, even bilateral

carotid occlusion does not necessarily give a bad prognosis for life(78). Of 100 consecutive cerebral artery thromboses, 10% returned to their former work ; one-third to part-time work ; 10% died in hospital, and one-third died within two years(47). Impaired visual spatial discrimination in right sided lesions may interfere more with vocational rehabilitation than aphasia does(101).

A third of patients dying with peptic ulceration have had a stroke(44). Lesions of the orbital and posterior parts of the frontal lobe are associated with renal tubular necrosis, perhaps due to renal vasoconstriction(210).

Atheromatous lesions of the circle of Willis in 1,175 autopsies were most frequent and severe at the upper and lower basilar, bifurcation of the carotid, first third of the middle cerebral and first part of the posterior cerebral arteries. Forty to eighty were the ages most affected ; however, 2% of those under 40 had severe atherosclerosis and 10% of those over 80 had none(10). Emboli, thrombi, plaques or intimal fibrosis were found on careful inspection of sulcal vessels, supplying all but two of 21 infarcts limited to one or adjacent gyri in the absence of deep lesions or trunk artery occlusion(229). Arab(7) describes an homogeneous refringent protein deposit in the muscularis layer of stenosed or dilated cerebral arteries of 50 patients, mostly hypertensive.

Only when there are ominous signs in malignant hypertension should blocking agents be used, particularly if there is occlusive vascular disease, for thrombotic epi-

¹ Harvard Medical School, Boston, Mass.

sodes are apt to occur as the blood pressure falls. Patients having small strokes are not apt to succumb to massive intracerebral hemorrhage, and are not helped by lowering the blood pressure(84).

Even keeping the room cool by air conditioning when it is hot and humid increased survival from ischemic brain lesions in rats (222).

When capillary pressure fell due to carotid artery occlusion and vision was gradually fading, McCulloch(143) was able to restore blood flow and save sight by lowering intraocular pressure, first with acetazolamide and then, cyclodiathermy.

Although the prothrombin test is highly reproducible, periodic monitoring is essential, particularly if patients are bleeding. Increasing microscopic hematuria is as significant as an increasing prothrombin time (147).

Ouren(162) has devised a new "thrombotest." Crude cephalin, thromboplastin, absorbed bovine plasma and calcium chloride form a single stable reagent which measures the coagulation factors of the intrinsic and extrinsic clotting systems in capillary blood, citrated blood or plasma. Matthews and Walker(140) confirm its superiority to the Quick test.

No benefit was seen in the half of a group of 51 patients with acute non-embolic, non-hemorrhagic strokes randomly assigned to anticoagulant therapy, and three died of massive intracerebral hemorrhage(139). Carter(33) found no benefit from anticoagulants in sudden, complete paralysis, but there seemed to be some benefit with ingavescent and incomplete paralysis. In a controlled study of patients with myocardial infarcts on token and adequate anticoagulation, the latter failed to prevent further infarcts or death, and hemorrhage was a serious and not infrequent complication(135). Denny-Brown(50) recommends anticoagulants only for embolism and for thrombosis would try to correct the low blood pressure, anemia, cardiac or vascular disease. Carotid surgery is successful only in otherwise healthy patients whose carotids are stenosed, not occluded(53).

In subarachnoid hemorrhage, the severity and duration of disturbed consciousness is the most reliable prognostic sign, though old

age and hypertension increase the risk(18, 170). Of eight patients with ruptured anterior cerebral aneurysm, 7 had infarcts in the vessel's distribution(21).

Of 244 patients with primary intracerebral hemorrhage, 20 percent had no blood in the cerebrospinal fluid(145). Angiograms were normal in 53, so ventriculography should be done if there is doubt. Prognosis was poorer with hypertension and coma. Deep hemorrhages had the highest mortality. Early tracheostomy was helpful.

Intracerebellar hemorrhage causes brain stem, rather than cerebellar symptoms(174). Vertebral angiography is not helpful. Three-fourths are seen in ventriculograms. McKissock(144) recommends evacuating the clot.

Cortisone treatments of half of 40 patients with polyarteritis nodosa possibly postponed death, but did not affect the outcome at three years. For a few it caused distressing complications(132). On steroid therapy only 2 of 23 eyes affected in giant cell (temporal) arteritis regained useful vision. However, steroids should be used and continued for two years if partial vision remains (184).

In congestive heart failure, mental symptoms are ominous, reflecting decreased blood flow and oxygen uptake(196). In cerebral degeneration decreasing oxygen uptake parallels dementia(117).

Migraine can be deadly(8). "Ophthalmoplegic migraine" is usually due to an aneurysm of the circle of Willis. Paroxysmal tachycardia is common in migraine families. Ergotamine may cause cardiac arrest in the patient with a slow pulse. Interstitial nephritis leading to uremic death is increasing, perhaps due to prolonged use of phenacetin by these patients. A reliable ergotamine tartrate makes treatment available and convenient, with side effects about equal to parenteral ergotamine(77, 207).

INFECTION

Tuberculous meningitis can be reliably differentiated from other lymphocytic meningitides by a Bromide serum-to-cerebrospinal fluid ratio below 1.4. Counting radioactivity in blood and cerebrospinal fluid samples 48 hours after giving 50 microcuries of Br^{82} by mouth gives clear cut results

independent of protein and cells in the cerebrospinal fluid(42).

Ophthalmological complications are equal whether or not tuberculous meningitis is associated with miliary tuberculosis. Nystagmus and pupillary disturbances are the most ominous complications(150).

The best treatment of tuberculous meningitis is intramuscular streptomycin, PAS and isoiazid(230). Steroids should be added in children under one year old or unconscious on admission(128) or for papilloedema(150).

In leprosy, a disorder of lipid metabolism was found in the essential cell(91). Diaminodiphenylsulfone (DDS) is the best drug for leprosy, but Ciba 1906 and Etisul are powerful adjuvants usable for a few months(46).

Pneumococcal meningitis is so fulminating it still causes 50 percent mortality in adults(180). It should be suspected in diabetes and skull fractures. Early craniotomy for decompression is often required, as well as intramuscular penicillin and intravenous sulfonamides.

Recurrent attacks of bacterial meningitis may be the only sign of skull fracture(22). Sharp-object wounds of the eyelid may penetrate the roof of the orbit, particularly in children(79). One ml. of fluorescein intraspinally and observation of nose, ears, etc. under ultraviolet light helps to identify cerebrospinal leakage(107).

Cerebral dysfunction 10 days after infection of ears or respiratory tract in children may indicate brain abscess(158).

In leptospirosis headache persisting beyond a week usually means an immune reaction meningitis which will be self limited as are the other brain and nerve symptoms at this time(54).

Boshes(23) has reviewed current management of fungus infections of the central nervous system.

In Toxoplasmosis, the parasite can be isolated from blood and occasionally cerebrospinal fluid in the acute stage. The dye test, hemagglutination and complement fixation tests become positive in that order. The skin test is positive after the acute stage. Pyrimethamine (a folic acid antagonist) increases the effect of triple Sulfona-

mide treatment eightfold, but it may depress the bone marrow(178).

Syphilis should not be diagnosed on the basis of one specimen of serum(131). Biologic False Positive (BFP) reactions become more pronounced during intercurrent infections. BFP's occur more than twice as often in infants whose mothers have BFP than those whose mothers have syphilis(152).

In neurosyphilis the treponema pallidum complement fixation tests (tpcf-50) is as sensitive as the TPI test(24). Tests using Reiter protein antigen, which is derived from a tube cultured spirochete and therefore cheaper, are as specific as the TPI test, but may be non-reactive in some older syphilitics(30, 173).

Two rapid reagin tests on unheated sera (RPRUS and USR) are as accurate as the VDRL(25), and can use the same blood specimen as is drawn for blood sugar if sodium fluoride is used as anticoagulant(98). A fluorescent treponemal antibody test (FTA) depends on an additional antigen similar to reagin(154).

The majority of 1,489 children with poliomyelitis had an acute onset and continuous course. One-fifth of the infants had no increase of cerebrospinal fluid cells, and half in all age groups had no increase of cerebrospinal fluid total protein at the onset of paralysis(123).

Mass use of vaccine at the time of an epidemic has no effect on the course of the epidemic. One injection now gives 50 percent protection, but four are needed for 95 percent protection. By increasing potency and the use of adjuvants, Salk(188) foresees a single injection technique.

Oral administration of attenuated virus has been effective and uncomplicated in children in Philadelphia(164), Louisiana(68), Mexico(187), Estonia-Latvia(186), Belgian Congo(118, 169), and Cuba(57). Intercurrent viral or other infections were not aggravated. Best results occurred when temporary dominance of the polio-viruses was achieved by giving large doses to the whole community at the season when other enteroviruses were least active. Previous Salk vaccination does not interfere. Ninety-five percent of adult non-reactors

were immunized to Types 1 and 3, but only three percent to Type 2(185).

Although genetic and serologic tests have found the viruses stable through several human passages(109), neutralization tests demonstrated changes(67) and neurovirulence for monkey spinal cord had developed in excreted viral progeny of a Sabin strain (153).

Vaccine protection against polio is making paralysis due to other viruses more conspicuous(119). But three-quarters of those with paralysis still have polio(148).

Spencer, *et al.*(208) discusses the cardiovascular complications of severe polio.

The cerebrospinal fluid is a better source of virus during the acute phase of aseptic meningitis, but may be sterile 6 days later (189). Complement fixation tests now reliably identify the viruses as compared to neutralization typing(74).

Forty different viruses were isolated from 713 patients(148). Enteroviruses were commoner in late summer and fall, lymphocytic choriomeningitis in winter and mumps in winter and spring. Death or serious sequelae most often resulted from arthropod born viruses and herpes simplex. Tuberculosis and fungus infection had a less acute febrile onset.

Mumps meningoencephalitis was established by isolation of virus from cerebrospinal fluid or hemagglutination tests in 38 percent of 56 patients(146). Sixteen had no salivary gland involvement. There were no serious sequelae. A third may have headache and nervousness a year later(156).

Herpes simplex can be activated by adrenalin(192).

Tissue culture and antigen precipitation techniques support the theory that Herpes Zoster is a reinvasion of tissues by latent chicken pox virus. Zoster complicates chronic rather than acute leukemia, particularly after radiation, alkylating agents or steroids perhaps due to a decrease of gamma globulin(197).

Although some reviews(60) say infectious mononucleosis causes many neurologic symptoms, Hoagland(87), applying rigid criteria, found them rare.

Brierly, *et al.*(28) report a subacute encephalitis of late adult life affecting mainly limbic areas of the brain. Three patients

were depressed, became progressively demented and comatose. One had temporal lobe seizures, but none had myoclonus or athetosis as in the Dawson-van Bogaert type. No virus studies were made. No virus was found in four cases of subacute necrotizing encephalitis(79).

METABOLISM

A case of Wilson's Disease with normal serum copper and ceruloplasmin supports Uzman's suggestion that the ceruloplasmin deficiency is secondary to a defect of protein metabolism producing proteolytic residues with high copper affinity(182). Cartwright, *et al.*(34) found poor correlation of ceruloplasmin levels and duration or severity of symptoms. Ceruloplasmin was low in normal newborn infants, an infant with idiopathic hypercupremia, some patients with sprue and a few with nephrotic syndrome. There was no improvement in Wilson's disease patients when ceruloplasmin increased in pregnancy, with estradiol or injections of ceruloplasmin. Ceruloplasmin deficiency can now be detected by placing a drop of serum on specially treated paper(1), or using starch gel electrophoresis(43).

Treatment to minimize copper absorption and increase its excretion may improve neurological symptoms but the liver is unchanged(190). One patient's fulminating course was aggravated by BAL and versenate(88). Four of five Wilson's disease patients had hypercalciuria, without hypercalcemia or increased alkaline phosphatase (126).

Hepatic stupor is more closely related to liver failure than to abnormal portal circulation(227). Chronic hypoxia interferes with the liver's ability to detoxify ammonia(5). The respiratory alkalosis of advanced cirrhosis may be compensatory to protect brain function(171). At autopsy, one of three cases of paraplegia in shunt encephalopathy had astrocytosis and demyelination of the pyramidal tract in the cord(233, 234).

Because non-hepatic patients with asterix due to chronic pulmonary, renal, cardiovascular disease or prochlorperazine toxicity were confused, Conn(36) ascribes the flap to malfunction of the reticular formation.

Ellenberg(55)* comments on a tendency for diabetic neuropathy to follow some stress such as surgery by one to four weeks, and compares this to the latency of infectious polyneuropathy, *etc.* Cord tumor should be ruled out by myelography if cord bladder or bowel appear in diabetic neuropathy(224). Larsen(115) has published a color photographic atlas of diabetic retinopathy.

Ophthalmoplegia develops and clears in relation to the thyrotoxic state of a tenth of thyrotoxic patients(193). Muscular weakness and atrophy, mainly proximal, developed in half of 42 hyperthyroid patients. Creatine was increased in all, and EMG changes were myopathic. Neostigmine did not alter fatigability. All responded to treatment of the thyrotoxicosis, most rapidly to iodine(72). Fifteen years after surgical treatment of Graves disease, ophthalmoplegia was unchanged in half, better in one-quarter, and worse in one-quarter(80). Twenty-eight patients in 18 families with goitre had congenital perceptive deafness, and in some cases defective vestibular function(64). Treatment of myxoedema stopped the convulsions of one patient(61) and cleared the ataxia of six(95).

Weakness was caused by hypokalemia in 10 patients with renal tubular disease(161).

The behaviour of two phenylpyruvic children, 4 and 7 years old, with I.Q.'s of 67 and 93, improved on a phenylalanine restricted diet(211).

NEOPLASM

Electronmicroscopy of brain tumors by Luse(130) gives added reason to believe glioblastoma multiforme is a grade 3 or 4 malignant astrocytoma. In oligodendroglioma mitochondria are usually few and small, but may be as large as nucleoli. The cells of meningioma of endothelial type resemble arachnoid cells. Neurofibromas have interlacing bands of collagen.

In a similar study(159) of tumor vessels, there was evidence of increased metabolic activity of the endothelium, an increase in periodicity of the collagen fibrils and numerous shunts, glomeruli, lacunae and aneurysmal vessels in glioblastoma multiforme. The vessels of astrocytomas and oligodendrogliomas were normal. Columnar

growth of metastatic bronchogenic carcinoma caused the vessels to be parallel.

At the Montreal Neurological Institute, 534 primary tumors of the brain, excluding 112 of the pituitary, were treated with tumor doses of 5000 to 6000 over 50 days via multiple portals(26). Most of the tumors had not been completely removable by surgery, yet all did better than those with similar tumors treated by surgery alone. There was no evidence of damage to the unshielded pituitary of 30 children. There were no corneal opacities. Only one adult retreated through the same portals had histologic evidence of post-radiation necrosis. Operative decompression is advised before radiation of inaccessible brain stem tumors.

Increased mortality in thiamine deficient mice with induced gliomas was due to increased bleeding in the tumor, rather than altered malignancy(27).

Three-quarters of 93 patients with acoustic neuroma had unsteady gait, half had vertigo, 80% had spontaneous nystagmus at the limits of binocular gaze, at first to the unaffected side. Audiograms were rarely normal, and only slight to moderate deafness suggested that the tumor was not an acoustic neuroma. Adequate masking avoided false, conduction type responses. The tumor involved the end organ of the 10% who had recruitment. In all of the patients caloric responses were abnormal, using 30° C. and 44° C. irrigations(52).

The natural history of 108 neuroblastomas varied greatly with tendency to hemorrhage and variable malignancy in different parts of the same tumor. Fifteen, most starting before two years; have survived 5 to 18 years(45).

Of 5,778 patients with malignant lymphomas, 795 had neurologic complications(49). Nitrogen mustards followed by x-ray was the treatment of choice for spinal lesions. Laminectomy should be done only for compression fracture. Although 90% of lymphoma patients and 50% of leukemic patients had cerebral symptoms, only 11 patients had intracranial tumor, all but one by extension. Ninety percent of the local involvement of cranial and peripheral nerves was by malignant lymphoma and half improved with radiation. Infections of

the central nervous system seemed related to lowered immunity, and all those with exotic infections died. Herpes zoster, in 162 patients, was not helped by radiation of the spine. Intracerebral hemorrhage occurred in 146 patients. Although vessel walls may be invaded in crises, bleeding was usually the result of thrombocytopenia so that iatrogenic marrow depression must be avoided.

Meningeal leukemia of high morbidity seems related to poor penetration of the blood brain barrier by the drugs and is apt to occur during a hematologic remission (48, 62, 198). It occurred in 25 of 150 patients with acute leukemia. Steroids and radiation of the skull benefited 75 percent. The danger of marrow depression prevents radiation of the spine, but intrathecal methotrexate produces a 4 to 6 weeks remission.

Of 33 patients with Hodgkins disease, the 13 who had pain after drinking alcohol had more eosinophils and more often had spontaneous pain, mediastinal involvement and leucocytosis (93). Eosinophil infiltration of a squamous carcinoma of the cervix was associated with alcohol induced pain (86).

Cerebral angiomas so increased venous pressure that compression of the jugular veins low in the neck caused rapid, prominent, usually ipsilateral swelling of the vein in all but one of 17 children (221). A bruit was audible over two of three spinal angiomas of children (141).

Five of 8 patients with symmetrical peripheral sensory-motor neuropathy associated with myeloma or malignant lymphoma had numerous metastases infiltrating the nerves (13).

In 363 consecutive cases of carcinoma of the lung, the brain was examined in 338, and 38 percent had intracranial involvement (81). The cell type was not related to frequency of intracranial metastasis.

The effect of various intensities of gamma radiation on the brain have been measured in terms of time to cause EEG abnormality (217).

Tumor cells were found in the cerebrospinal fluid of 12 of 64 patients with histologically verified tumors, and in 8 were the first proof of metastasis (11). Marks and Marrack (137, 138) suspend the sedimented cells from the cerebrospinal fluid in 3 or 4 microliters of bovine albumin and 1 per-

cent EDTA. The suspension is smeared on cover slips as for a blood smear and stained with Leishman's. The abnormal cells tend to be large and occasionally syncytial. The nuclei are large, sometimes multiple or mototic, or have large nucleoli.

BASAL GANGLIA DISEASE

Opisthotonus, torsion spasms, oculogyric crises, trismus, other painful muscle spasms and akathisia continue to be reported not only from dimethyl and piperazine derivatives of phenothiazine, but also reserpine and deanol (31, 66, 110, 200, 220). They may occur when the drug is started or the dose increased, or may be precipitated by an acute infection or dehydration. The phenothiazines produce a purple-brown color when 1 ml. of 10% ferric chloride and 1% hydrochloric acid is added to 3 ml. of the patient's urine. Mild cases responded to barbiturates. Severe cases may require parental caffeine or diphenhydramine (Benadryl).

Most of 40 patients with basal ganglia diseases had increased urinary catechol amines (12).

Parkinson patients with abnormal EEG's have a poorer prognosis for surgical treatment (58). Five hundred chemothalamotomies by Cooper (37) produced enduring relief of tremor and rigidity in 85% and oculogyric crises were ameliorated. Below age 65, he would wait to operate until ability to earn a living is threatened. Mental deterioration, psychosis and pseudobulbar palsy are absolute contraindications. Physiological old age and advanced medical disease are relative contraindications. Mortality was 2.4%. Paralysis was permanent in 3%, transient in 6% and other transient symptoms occurred in 10%. Similar observations are made regarding thermal lesions (212). A case is reported where the ventral medial globus pallidus has been destroyed without effect on Parkinsonism, but the chemical had passed along the anterior commissure to cause necrosis on the other side (226). The psychologic effects of stereotactic lesions are non-specific and not related to the area coagulated (155).

Essential tremor of 210 patients stemmed from 9 ancestors (115). The onset was usually at 50 years (10 to 70 years). Onset and

progress varied in the same family. The tremor was sometimes greater in one limb. Seventeen patients had some rigidity.

Twenty-four cases of tremor are now reported from New Guinea, 170 miles from the Kuru area(228). There are associated pyramidal, extrapyramidal or cerebellar symptoms.

MULTIPLE SCLEROSIS

In a review, Schumacher(194) reports a higher than chance incidence in relatives. Although fewer cases start in warm climates, climate does not affect the course. Average life expectancy is 21 years. There are more recurrences and shorter survival with late onset. A case that is mild for the first five years is apt to remain mild. Of patients ambulatory when first seen, 40% are still ambulatory 15 years later, 25% are helpless and 33% are dead. The best treatment is supporting and sympathetic, avoiding fatigue in the active stage(112).

Careful culturing of spinal fluid for 2 to 6 months was negative for spirochetes(142). Infrared spectrophotometry of serum lipid in Multiple Sclerosis was normal(65). Electrophoretic partitioning of cerebrospinal fluid and serum proteins of 23 Multiple Sclerosis patients was normal except in six patients with a short course and abnormal gold sol who had increased gamma globulin and decreased albumin in the cerebrospinal fluid(29).

Cooper reports relief of cerebellar tremor by chemothalamotomy in 10 of 90 patients (38).

OTHER CENTRAL

NERVOUS SYSTEM DISEASE

Victor, *et al.*(219) describes 50 alcoholic patients with an apparently malnutrition syndrome of gradually increasing ataxia, most conspicuous in the legs. A degeneration of the cerebellar cortex of the anterior vermis and hemispheres is best demonstrated on sagittal section. The olives and less consistently the medial cerebellar and the vestibular nuclei may be affected.

Carbon monoxide may be demonstrated for up to 3 weeks after chronic poisoning due to binding with other tissues(71).

Narcoleptic patients may have a partial Pickwickian Syndrome(202).

Magnesium deficiency may cause depression, irritability, ataxia, weakness, convulsions, low voltage ECG and focal EEG slowing(83).

Calcium EDTA is the best treatment for lead intoxication, but it must be used cautiously in children who may need cerebral decompression by craniotomy or intravenous urea(225).

Fifty cases are now known of progressive ataxia of infancy and early childhood with telangiectasea of the conjunctivae and skin of ear and nose(195).

Retinitis pigmentosa and congenital deafness seem to be different manifestations of the same gene and many patients have labyrinthine disorder and mental deficiency(82).

In Hurler's disease, but not in normal relatives, reticuloendothelial cells are found to contain inclusion bodies with a central zone staining as a mucopolysaccharide and a peripheral unstained zone(96).

In Gaucher's disease, the increased serum acid phosphatase seems to be distinctive in its reaction and so may be of diagnostic value(215). The defect of cerebroside formation appears to be catabolic(216).

At autopsy a patient with congenital universal insensitivity to pain had no abnormality of structures concerned with pain(14).

Despite digitation of the skull on x-ray, 37 cases of craniostenosis were asymptomatic and mentally normal. Papilloedema and optic atrophy are absolute indications for craniotomy(76).

Surgery may arrest the progression of symptoms of spinal dysraphism(94). The "split notocord syndrome" of developmental posterior enteric remnants may have associated visceral abnormalities of the chest and abdomen(16).

Convulsions during the first days of life of 374 patients were the result of major brain pathology. Those with subdural hematoma were often precipitated by external stimuli and preceded by vomiting. Cold often caused convulsions, but there were no febrile convulsions in the group, nor in children with fevers as high as 108°F.(40).

Toxemia of pregnancy, prolonged labor or anoxia at birth did not result in more convulsions in 762 at age 10 to 14 than in controls(102).

Birth trauma to the vertebral arteries

may cause ischemic changes of the brain stem important in cerebral palsy(232). Difficult breech delivery or vertex delivery with the arm over the head may injure the spine at the cervico-thoracic junction with non-progressive motor and sensory signs to this level, but not necessarily mental retardation(121).

Cervical discs compressing the cord-like tumors, may require operation, but with lesser lesions, or when the diagnosis is in doubt, patients are better given a three-month trial with a Minerva Collar(32). Cinoradiography confirms the inadequacy of other collars(99).

Lumbar discs, when they cause loss of bowel or bladder control require urgent surgery(199).

Serum transaminase is too insensitive and nonspecific to be useful in diagnosis of neurological diseases(213).

CRANIAL AND PERIPHERAL NERVES

One in 25 chronic alcoholics with peripheral neuropathy gradually develops blurred vision, a central or centrocecal scotoma and usually pallor of the disc. The papillomacular bundle degenerates in the optic nerve, chiasm and tract. Most improve on food and B vitamins, but the exact nutrient responsible is not known(220). A similar lesion is reported in B₁₂ deficiency(59).

Retinal hemorrhages are common in megaloblastic anemia, but rare in normocytic anemia, suggesting that anemia is not alone the cause(39). Retinal exudates and hemorrhages after massive gastrointestinal bleeding are related to the brief fall in blood pressure, not the anemia. Focal anoxia of the retina may be the cause(165).

Glew(73) reviewing observations on papilloedema proposes that it is due to optic nerve edema associated with cerebral edema.

When a child suddenly develops a central scotoma pneumoencephalography may be needed to exclude tumor. But for optic neuritis, no treatment is helpful. Fifteen of 19 recovered completely(103).

Complete congruity of visual fields following 24 temporal lobectomies suggests that incongruity in cases of tumor may be due to pressure on the optic tract. The fibers looping most anteriorly represent the part

of the field nearest to the upper vertical meridian(223).

Vertical eye movements are mediated by bilateral parmedian pathways just ventral to the median longitudinal fasciculi(15).

Diabetes and Multiple Sclerosis each account for one-sixth of abducens paralyses. They clear in an average of 3 months, independent of treatment. One-tenth are due to syphilis and without prompt penicillin therapy, they are permanent(201).

Nystagmus of labyrinthine origin (motion sickness) is suppressed by antihistaminics, but not hyposcine, largactil or nembutal(100). In appraising positional nystagmus, the patient's head must be turned far to either side and hyperextended(191).

In a controlled study, potassium and sodium was found to have no relation to Meniere's attacks(75). Nicotinic acid kept 48 patients free of relapses for 3 to 6 years.

Strict criteria for diagnosis of Guillain-Barre Syndrome are outlined by Osler and Sidell(160). If symptoms were still progressing, steroid therapy may help(134).

Even if the whole area of pain is not anaesthetized, the pain from a more proximal lesion is relieved longer than the duration of the nerve block(104). Cooling with ethyl chloride or freon is an effective counter-irritant to relieve some post herpetic neuralgias(213).

Pilocarpine was the only beneficial treatment of the tricesylphosphate myeloneuritis of Morocco(70).

The amount of hypertonus and spasm are more reliable guides to the severity of tetanus than the duration of the latent period. Tracheostomy, curarization and artificial respiration are advisable in severe cases. A toxic myocarditis as in diphtheria is apt to cause fatal hypotension(2).

Polyneuropathy in rheumatoid arthritis carries a serious prognosis. It is not always related to steroid therapy. There is no effective treatment(85, 209).

Peripheral entrapment neuropathies of the lower extremities have been reviewed by Kopell and Thompson(108).

MUSCLE

Myasthenia Gravis has been reported in one of monozygotic twins(3). The abnormally long and multiple endings at the

motor end plate in myasthenia described by Coers have been confirmed (19, 133). Electronmicroscopy of the myoneural junction disclosed seven layers of pores, perhaps for released acetylcholine (20).

Most of 65 myasthenic patients reach their maximum requirement of medicines in the first year (167). Instillation of cholinergic drugs in the conjunctival sac lessens ptosis and diplopia in a few patients without ill effects (120). The ganglionic blockade by monoamine oxidase inhibitors is discussed by Gertner (69). A new oxime has an additional atropine-like action (125).

Kreel, *et al.* report that thymomas are three times as apt to be malignant in myasthenics as in non-myasthenics. X-ray treatment before thymectomy tends to make control more brittle. Pre-operative tracheotomy is advisable and the patient should be carried on the minimum of medication to cover respiratory needs and so avoid cholinergic crises.

We really need a method for estimating intra-muscular electrolytes to determine whether muscle membrane permeability is altered in myotonia (163). Lowered serum potassium is not effective in control of myotonia (124). Hyperostotic changes were noted in the skull of many patients with myotonic dystrophy (35).

The weakness of progressive muscular dystrophy is apt to cause a hypoventilation syndrome (105). Cardiac involvement is not related to the severity of the skeletal muscle disease (92). In pseudohypertrophic muscular dystrophy, the first changes are vacuolization of the sarcoplasmic reticulum (118). In the hereditary dystrophy of mice, breakdown begins in the myofilaments (183) and labelled glycine studies indicate an accelerated turnover of muscle proteins (113). In a controlled study of 33 muscular dystrophy patients, Vitamin E had no effect (17).

CLINICAL EXAMINATION

Meyer and Barron (149) have shown that Brun's "frontal ataxia" is really frontal lobe apraxia. There is apraxia of all leg movements, particularly bilateral movements. There is rigidity, gegenhalten and difficulty initiating movements. Hypokinesia and bradykinesia may even reach catatonia. Not

all have foot grasp. (There is not the sensory loss of parietal apraxia.)

Somatic sense of depth of space is distinct from touch and surface space perception, and appears to be a parietal lobe function (175).

Tapping the flexed index finger on the thumb at the interphalangeal joint as quickly and precisely as possible is a helpful test of coordination (63).

In non-diabetic patients, the reinforced deep reflexes of the legs are absent in one percent of patients over or under 60 years old (56).

An elaborate electromyographic study indicates that the Babinski sign is the result of encroachment of the receptive field of the normal flexion reflex on that of the normal extension reflex (114).

Cortical lesions causing a positive optokinetic response are parietal (206).

CEREBROSPINAL FLUID

On electrophoretic fractionation of cerebrospinal fluid gamma globulins (serum proteins were normal) in Multiple Sclerosis and Neurosyphilis, the increase was mainly in gamma 1, 2 and 3. In subacute sclerosing encephalitis, it was mainly in gamma 4 and 5 (129).

Only prolonged elevation of blood sugar affected cerebrospinal fluid glucose levels (136). The disappearance of sugar from cerebrospinal fluid in meningitis appears due to the increased phagocytic activity of the white blood cells (168).

Yellowing of the cerebrospinal fluid is not diagnostic of the cause of the patient's jaundice, except that with pleocytosis it suggests leptospirosis (181).

PROCEDURES

Phenol myelography can relieve spasticity, but damage to sacral roots paralyses the sphincters and dorsal root damage leads to decubiti. It should not be used in active Multiple Sclerosis and only circumspectly in ambulatory patients (127, 157).

Spinal complications or aortography are due to arterial access of dye to the cord parenchyma. They are avoided by using the prone position, avoiding barbiturates and using small injections of Hypaque (206).

Five hundred cerebral angiographies

with Hypaque at Mt. Sinai Hospital caused only 6 percent complications(205). At the Mayo Clinic(9) 9 percent had permanent and 11 percent transient complications.

Motor nerve conduction velocity is normal in polio but lowered 40 percent in poly-neuropathy(97).

The urinary tract can be kept sterile by strict aseptic care of the drainage system (51, 151).

ALCOHOLISM

KARL M. BOWMAN, M.D.¹

Jellinek(3) considers that there is a physiological dependence in alcoholism similar to that found in morphine addiction and in barbiturate addiction and that the convulsions of the alcoholic are commonly brought about by withdrawal of alcohol. He feels that further study of the evidence on both sides should be carried out but concludes, "The alcohol withdrawal syndrome is so well documented that its existence can hardly be denied and under certain conditions . . . it may culminate in delirium tremens."

Krystal(4) in a study of 700 patients with delirium tremens made careful physiological studies including the electrolyte levels in the blood serum, such as sodium, chlorides, potassium, and magnesium. He felt that one of the important precipitating factors in delirium tremens was the withdrawal of alcohol which was relieving the patient's anxiety and depression. He felt that delirium tremens was a syndrome caused by the following factors : (1) water deficiency, (2) salt deficiency, (3) magnesium deficiency, (4) inability to wall off invading organisms, (5) brain swelling, and (6) the pharmacothymic crisis.

Friedhoff and Zitrin (2) compared two groups of cases of delirium tremens. Both groups received vitamins, intravenous fluids, and where necessary, antibiotics. Group I received chlorpromazine and group II received paraldehyde. The symptoms subsided on an average of 8 days for group I and 6 days for group II. It was concluded that paraldehyde appeared responsible for the more rapid recovery in group II. Chlorpromazine was felt to be valuable in abolishing nausea and vomiting.

A Norwegian study of delirium tremens

(6) found that there were increased blood serum levels of glutamic oxalacetic transaminase (GOT) and ornithine carbamyl transferase (OCT) and felt that this was due to liver pathology. However, the authors felt that increased GOT and OCT could not be considered as the main cause of delirium tremens since some of their cases did not show increase of these two substances.

A long French article(5) entitled "Injectable meprobamate; effective treatment of states of acute alcoholic delirium" reported the previous high mortality rate in delirium tremens and its decrease in 1958-59 to one-fifth of what it had been in 1951. After experimenting with various drugs and finding chlorpromazine and reserpine unsatisfactory, the authors tried meprobamate and found it most satisfactory. It is noteworthy that the authors in addition to meprobamate by intramuscular injection used vitamin B-1 and B-12 and strychnine and intravenous 25% alcohol in glucose solution in gradually reduced amounts. Barbiturates were not given. There were no fatalities in the 83 cases treated and the condition cleared up in 3 days in all but one of the cases. The authors state that under this treatment restraint was not necessary. Isolation, however, was employed and good nursing care and constant observation of the patient was emphasized as an important factor in recovery.

A number of other reports stress the authors' opinions upon specific drugs in the treatment of acute alcoholism and delirium tremens. Orland and Camden(9) used triflupromazine hydrochloride in the treatment of acute alcoholics in a county or city prison. They found that 212 of 252 prisoners treated by the oral administration of 25 mg. of the drug every 4 hours, and in some

¹ Professor of Psychiatry Emeritus, Univ. of California Medical Center, San Francisco 22, Calif.

cases running the total dosage up to 400 mg. in 24 hours, showed marked improvement. Forty patients showed no improvement or their symptoms became worse.

Baroody(1) reports the use of trifluoperazine (Stelazine) in 23 cases of delirium tremens and felt that it was of value. He stated that further studies were needed to determine how valuable this drug is. Since these cases were given chlorpromazine or promazine intravenously in the beginning and received fluids, glucose, vitamins, magnesium, diuretics, tranquilizers and steroids, the role of trifluoperazine is as yet undetermined.

Much has been written about the effect of tranquilizing drugs in potentiating the effect of alcohol. Meprobamate, although a hypnotic and not a tranquilizer, has been shown to potentiate the effect of alcohol. Recently a study(12) was made on the effect of paraldehyde. Albino male mice given alcohol and then an hour later given paraldehyde showed a marked increase in the toxic effect of alcohol. The authors question whether it is safe to give paraldehyde to individuals under the influence of alcohol.

A recent study(10) of patients given an intravenous injection of amino acids concludes that amino acids accelerate the rate of alcohol disappearance in the blood.

Miller and Dvorak(7) report a method of group conditioning in which 4 patients were simultaneously conditioned to aversion to alcohol. They concluded that group conditioning is not only possible but has certain advantages over individual conditioning.

Minto and Roberts(8) report experimental work and prolonged use of Temposil in 27 patients and compare its use with that of disulfiram. Temposil does not produce the unpleasant side effects seen with disulfiram, and so patients will take it more regularly. When alcohol is taken within 24 hours of having taken Temposil, an acetaldehyde reaction occurs within 15 minutes. All patients in this series showed some degree of this reaction, whereas alcohol-disulfiram reactions are less predictable. The Temposil reactions are less severe than those with disulfiram, and they can be rapidly minimized by intravenous injection of an antihistamine, whereas disulfiram reactions are not easily modified. Patients(6) who took alcohol

within 24 hours of taking Temposil could reduce the intensity of the symptoms by walking about briskly. Only 1 patient in the series could not have walked thus about because of the severe reaction. Temposil's main disadvantage is the increased desire to drink in the early stages of alcohol-Temposil reactions, but this can be overcome by close observation of the test reactions before beginning long-term use. The data showed that 100 mg. of Temposil are better than the 50 mg. suggested by other workers.

Scott(11) in a study of 122 male alcoholics and 21 female alcoholics, all of whom were divorced, concluded from the patients' discussions of their sex lives that sexual immaturity, not homosexuality, is the basic characteristic of the alcoholic. The alcoholic, although actively heterosexual, cannot take on the responsibility of a permanent relationship.

GERIATRICS

KARL M. BOWMAN, M.D., AND BERNICE ENGLE, M.A.¹

The results of a 3-year survey, carried out by the New York State Department of Mental Hygiene, of over 2,000 persons past age 64 in New York City old age homes, nursing homes and state hospitals, have indicated that 88% of those in nursing homes and 94% of those in state hospitals had chronic brain syndrome of some degree (11). The severe form predominated in state hospital patients, of whom 89% (many doubtless had improved since admission) were still eligible for certification. These data belie claims of "overuse or abuse of state hospitals, on either medical or moral grounds, through the unwarranted admission or retention of aged patients."

A 2-year study (1957-59) of 191 Saskatchewan geriatric patients, 137 admitted to a mental hospital, 54 to a general hospital psychiatric unit, showed the disproportionate number of senile and physically ill persons in the state hospital admissions, of whom only 62 (45%) improved enough to warrant discharge compared with 53 (98%) of the general hospital group. At the 1959 follow-up, 53 (39%) of the mental hospital, compared with 9 (16%) of the general hospital group had died. Thus even with vigorous care, mental hospital patients with physical disease died more precipitously than did their fellow patients in a hospital more suited to general treatment (16).

In the Geriatric Research Project at Langley Porter Neuropsychiatric Institute, psychiatrists and social scientists have reported on 534 patients aged 60 and above, first-time admissions in 1959 to the psychiatric ward of San Francisco's city-county general hospital, of whom two-thirds were placed in state mental hospitals. This group was compared with another group of 600 men-

tally healthy persons living in the community, matched as to age, sex and living arrangements. According to preliminary analyses, average mental ability of the group showed a progressive decline in the hospital group from age 60 (the earliest age measured), whereas no such decline was seen until age 75 in the community group. In the hospital group 62%, compared with 33% in the community group, had incomes of only \$1500 or less. Most striking, in the hospital group, was the high incidence of serious physical illness; 70% required daily care just for physical disability, and, in more than 40%, admission to the psychiatric ward had been precipitated by acute behavioral disturbances in response to acute physiologic disorders. As a group the 534 hospital patients were seriously ill psychologically or physically—more often both.

Institutes and divisions of gerontology have been set up in recent years in 16 universities, some of them with research programs.

In a long and interesting report from England, Roth (13) has discussed the high proportion of somatic illness in geriatric mental patients as a whole.

Blain (2) reported to a group of general medical practitioners on an American Psychiatric Association survey of 3,500 professional persons, many of whom stressed that doctors need to treat the aged as intelligent human beings, to understand psychological medicine, to be aware of the patient's financial problems, and to refer him when necessary to social agencies.

From his extensive survey of mental health research, Deutsch (6) has noted that the use of open wards and new drugs has helped reduce the total state hospital population for 3 years, 1955-58; but this reduc-

¹ University of California, San Francisco Medical Center, San Francisco, Calif.

tion, though significant in the face of an increased general population, amounted to less than 1% in 1958.

Recommendations of various new drugs continue. Wayne(17) considers analeptics as sometimes of value; their essential ingredients, metrazol and nicotinic acid, are aimed at increasing blood supply and oxygenation. In depressions of the aged, electroconvulsive therapy effects prompt symptomatic relief. Tranquilizers, properly used, may decrease the aged patient's anxiety and agitation, but their excessive use may deprive him of the self-realization still possible. The dosage should commonly be reduced as time goes on, according to Howell(12); in many cases the use of tranquilizers has masked serious underlying diseases. Sanen(14) warns that tranquilizers may increase the difficulty of evaluating the clinical symptoms of ischemic heart disease in senile and psychotic patients. A British report(8) rates ischemic heart disease as the second most disabling disease in men over age 70.

The amount of hormone released by the thyroid gland, though it decreases with age, remains constant in the blood; and the giving of thyroid substance to the aged does not make them spry, but only nervous and trembly; hence the lethargy of the aged is not due to hypothyroidism(10).

The preliminary results of a study of intensive psychotherapy for a 9-month period with 12 patients aged 75 to 95 were encouraging, even in those with evidence of organic changes(4).

Dr. Anna Aslan in various reports(1) on procaine therapy (a 2% procaine solution, with a Ph of 3.3 to 4, called H₃), first given to 189 aged institutionalized persons in 8 to 9 monthly courses with interim rest periods, claims to prolong life and to relieve many disorders, from arthritis to failing memory. Its use as a prophylaxis is now being investigated. Several authorities have strongly questioned these claims; Droller(7) considering the evidence inconclusive, and both Freeman and Insley(9) expressing doubt of the drug's efficacy. The Swiss investigator, Verzar(15), has found no differences in life-time, general appearance and biological age of certain fibers between rats treated 14 to 30 months with large doses of pro-

caine and untreated rats from the same litters; but these experiments "do not preclude a possible stimulating influence of procaine in humans." A Russian, Dr. J. F. Zhordaniya(19) reported that the revascularizing of a senile dog's ovaries restored fertility in 25 enfeebled and aged dogs, though no attempt was made to breed them. The experiment was called a step in the direction of prolonging life.

Bourlière(3) includes in a report on gerontological activities in France a study on the duration of sleep in 380 healthy persons, aged 30 to 80: the average value was 7 hours, 20 minutes; the duration remained remarkably constant throughout life for those not regularly using a narcotic, and was little affected by the subject's sex and intellectual background. A study of attitudes toward retirement in 264 white collar and manual workers gave poor health and fatigue as main reasons for stopping work in half the group; hence a postponed age of retirement would not greatly increase the economic benefits. Van Zonneveld(20) reports that about a third of Dutch men aged 65 are still at work, and some employers offer part-time work to pensioners. Italy early in 1960 held its first examinations for a university degree in gerontology and geriatrics.

Williams(18) from tests of 100 British persons past age 65 would assess a wide variety of abilities, emphasizing individual test performances and not the total score. Clark(5) has concluded, in a series of physiological and psychological measures of 102 subjects aged 20 to 70 that, "at the level of this analysis, aging occurs along a single dimension, measured best by blood pressure, lens accommodation and sound threshold and less well by ability and speed tests."

Tests of a cross section of 250 elderly persons in the Duke University geriatric study have indicated that in a person aged 60, with an IQ of 116 or above, mental ability drops very slightly with aging; with an IQ of 86-116, it declines gradually and moderately; with an IQ of 85 or less, it drops markedly.

The American Association for the Advancement of Science held a symposium on aging late in 1959. *Handbook of Aging and the Individual*, edited by J. E. Birren, 1959,

is a comprehensive survey of recent research and other information on aging. R. S. de Ropp's *Man Against Aging*, 1960, is a competent review of the topic for the layman.

EPILEPSY

WALTER J. FRIEDLANDER, M.D.¹

PHYSIOLOGY AND BIOCHEMISTRY

"Isolated" cortex became hypersensitive to acetylcholine(1) (the suggestion that followed was that just such a partial isolation of the cortex secondary to trauma, tumor, *etc.*, may be an important factor in the production of seizures). Stimulation of the posterior hypothalamus decreased cortical seizure threshold(2) and stimulation, particularly of the rhinencephalon, produced seizure activity in the hypothalamus(3). Various "autonomic" responses were obtained by stimulation of human anterior cingulate area(4) but they were so rare and inconstant that the authors questioned whether they represented "normal" functions of this area; in the monkey, epileptic foci in the amygdala produced a different type of seizure (convulsions of limbs and trunk, head turning away from the lesion) than foci in the hippocampus ("twitching" of the upper lip, head turning to side of lesion)(5). Based on clinical material, ictal depression was more frequently associated with diffuse temporal lesions whereas ictal fear was more frequently associated with

temporal cortical lesions(6), particularly on the left(7); seizures arising from medial and superior border of the cerebral hemispheres frequently produced auras of visceral, genital or anal sensation, postural movements, and sensory or motor phenomena of the lower extremity(8). Of considerable interest were the different types of responses obtained in monkeys by electrical self-stimulation of implanted electrodes(9): self-stimulation of the anterior thalamus produced an increase in self-stimulation and then spike-wave activity in the septal region, self-stimulation of the posterior hippocampus produced a seizure burst and then increased self-stimulation, and self-stimulation of the amygdala produced rapid self-stimulation until a seizure burst occurred to be followed by prolonged absence of self-stimulation.

Among the biochemical studies published last year, some were: experimental focal seizures are associated with an immediate decrease in the epileptogenic area of glutamic acid, glutamine and glutathione but no significant change in gamma-aminobutyric acid (GABA)(10); increase potassium or decrease calcium concentration in-

¹ National Veterans Epilepsy Center, Neurology Section, VA Hospital, Boston 30, Mass.

creased GABA in vitro(11) while ammonium hydroxide increased GABA in vivo(12, 13); a mirror focus to an experimental epileptic focus had a decrease in the blood-brain-barrier to GABA(14); and GABA action is probably not merely a simple blockade of excitatory activity(15, 16, 17). In contrast to the concept that "all seizures are one"(18), Stone, *et al.*(19) review showed how a number of different convulsants have different basic physiological or metabolic actions.

SYSTEMIC CHANGES

ASSOCIATED WITH SEIZURES

Cerebrospinal fluid (c.s.f.) glycoproteins have been reported as normal in epileptics(20) or as normal in "genuine" epilepsy but increased in post-traumatic epilepsy(21); the transaminase was variously reported as elevated in patients with grand mal epilepsy(22) transiently increased after a generalized convulsion(23, 24) and increased with seizure activity(25); c.s.f. gamma-globulin was found normal in patients with petit mal but slightly elevated in patients with grand mal(26); c.s.f. malic dehydrogenase was lowered but not significantly in patients with seizures(27). A seizure or series of seizures increased c.s.f. ammonia(28), decreased serum-c.s.f. barrier to protein(29), produced a significant transient increase in a "bradykinin-like hypotensive polypeptide" in the brain(30), transiently increased and then transiently depressed protein-bound iodine(31), increased plasma catechol amine concentration if the seizures were not modified by succinylcholine(32), produced no change in brain amine oxidase content(33), produced ventricular dilatation as seen on pneumoencephalography(34), and altered specific areas of the adrenal cortex(35, 36). A convulsion may produce a significant myoglobinuria(37). The serum of epileptics was more toxic to experimental animals than that of controls(38, 39, 40, 41). Metastases from experimental cancer in rabbits were increased by electric convulsive therapy(42).

ETIOLOGY

Incidence of seizures in patients with various conditions was reported as: 42%(43) or 28%(44) after head injury, 95%

with cerebral paragonimiasis(45), 44% with microcephaly(46), 6% with progressive muscular atrophy, 29% with Oppenheim's disease, and 6% with myasthenia gravis(47), 27% of idiots and imbeciles(48), 30% of children with chronic lead poisoning(49), 13% of children with central nervous system lupus erythematosus(50), 50% with cerebral sequelae of air embolism(51), and 5% of psychotics admitted to Peking Mental Psychopathic Hospital(52) or 6% of an English mental hospital population(53). Focal seizures may occur 2 to 4 years after recovery from tuberculous meningitis(54). A study of 15 cases of seizures occurring during influenza suggested that the infection may precipitate convulsions in susceptible individuals but that the effect of the infection is only temporary(55). Ten out of 88 patients who had temporal lobectomies for psychomotor seizures were found to have congenital cerebral arteriovenous malformations(56); tumors accounted for 57% of the small focal lesions found in the temporal lobe after lobectomy for psychomotor epilepsy(57). The first symptoms of a glioblastoma were either focal or generalized seizures in 9% of patients and, on the average, these seizures preceded the hospital admission for the tumor by a period of about 1 year(58); seizures of late onset were a symptom of a brain tumor in 22%(59) or 19%(60) or rarely(61); in children up to 15 years of age, seizures were frequent with supratentorial, slow growing tumors(62); 89% of cases with seizures beginning in the foot had brain tumors(63). Muscle biopsies from 30 epileptic children revealed angiitis of small and medium calibre vessels in 7 cases(64); convulsions were part of the symptomatology in 4 out of 7 cases with noninfectious granulomatous angiitis(65). Among the less common causes of seizures that were reported were: Hypaque cerebral angiography(66), low G tolerance(67), pyridoxine dependency(68), scleroderma(69), folic acid given for the megaloblastic anemia due to phenobarbital(70), and poliomyelitis vaccination(71). There was a positive family history of convulsions in 15% and a positive past history of convulsions in 11% of a large group of patients with migraine(72). Kellaway and Druckman(73) suggested that all cases of "breath-holding"

seizures and episodes of unconsciousness associated with noxious stimuli are due to reflex cardiac arrest.

CLINICAL ASPECTS OF SEIZURES

Hunter(74) presented an historical review of status epilepticus; he suggested that the increase incidence of status is largely related to the use of active anticonvulsant drugs. Further series of patients with headache and/or abdominal pain as a form of epilepsy have been reported(75-82); these may respond quite well to anticonvulsive medication. Nystagmus may be a part of a petit mal seizure(83). The subject of epilepsy *cursiva* (running seizures) was discussed(84); the running may be preictal, ictal, or postictal. Two more cases of muscogenic epilepsy with temporal lobe foci were reported(85, 86). There were two reports concerning reading epilepsy(87, 88); Critchley, *et al.*(87) suggested 5 different mechanisms that may produce this syndrome: (a) pattern vision akin to photic stimulation, (b) repetitive proprioceptive impulses from the eye muscles and possibly the lips, *etc.*, (c) attention to reading with exclusion of awareness of environment, (d) emotional reaction to subject matter and (e) conditioned response to the circumstances of reading. Television has been indicated as the precipitating factor of seizures in several cases(89, 90). Ionasescu(91) reported some interesting cases of paroxysmal disorders of body image; where the focus was in the parietal lobe rather than the temporal lobe, there was more likely to be involvement only of the extremities. Anastaspoulos, *et al.*(92) presented 3 female patients with temporal lobe seizures and endocrinopathy. There was an interesting report of 3 siblings all of whom had seizures in utero as well as in neonatal life(93).

PSYCHOLOGICAL AND SOCIOLOGICAL

Psychological tests found that patients with "nonfocal (centrencephalic)" epilepsy did more poorly on tests of attention than patients with focal (temporal and frontal) epilepsy and patients with bilateral, independent (EEG) temporal foci had somewhat lower memory quotient than those with a unilateral temporal foci(94). Chil-

dren with an organic convulsive disorder showed greater variation in psychological subtest scores and a greater decrease in verbal I.Q. when retested than did children with a nonconvulsive organic disorder; normal children had higher I.Q.'s on initial tests and greater variation between verbal and performance I.Q. than was found in the other two groups(95). Lesions in the dominant temporal lobe were accompanied by difficulties in verbal recall while lesions in the nondominant temporal lobe were accompanied by impairment in comprehension of pictures; ablation of the temporal lobes for seizures accentuated these defects(96). Psychotic episodes associated with seizures were: (a) coincident with the seizure, *e.g.*, during "petit mal status," (b) during the postictal state, or, (c) in the case of temporal lobe foci, manifestations of "pre-seizure or subseizure excitation in the parahinal structures"(97). Goldie and Green(98) presented an interesting patient whose seizures could be provoked by rubbing his face; suggestion under hypnosis or anticipation of stimulation could produce the same effect, *i.e.*, the psychological stimulus was just as effective as the actual rubbing. Flynn and Wasman(99) demonstrated that hippocampal discharge did not interfere with "learning." Several studies of the socio-economic effects of epilepsy suggested that factors other than the seizures per se were often very important in the patient's apparent lack of adjustment(100, 101). Caviness(102) presented the interesting results of a Gallup poll showing the improving attitude of the public toward epilepsy over a ten year period.

THERAPY

Koch and Woodbury(103) suggested that Dilantin increased the neuron's "sodium pump" in contrast to Diamox's decreasing the permeability to sodium so that both drugs may end up with a decreased intracellular sodium and increased intracellular potassium but they did so by different mechanisms. Strobos and Spudis(104) reported that Dilantin influenced the seizure threshold but not the spread of a seizure while phenobarbital acted by limiting the duration and spread of seizure with but little effect on the threshold; on the other

hand, both Dilantin and phenobarbital but not Tridione were reported to decrease electrically induced cortical seizures(105). Studies were reported on: Mysoline(106, 107), Phenurone(108, 109), Elipten(110, 111, 112), carbonic anhydrase inhibitors(107, 113-118), several succinamides(119-122), meprobamate(123, 124), phenothiazines(125, 126), Mesantoin(127, 128), Xylocain(129, 130, 131, 132, 133, 134), quinidine(135, 136), two Indian plants (Jatamansone(137) and acorus calamus linn(138)), Ro 1-8294 (4-phenyl-4-methylpyrrolidione)(139), 2-ethyl-cis-crotonylurea(140), alpha-amino-gamma-diphenylhydantoxylvaleric acid(141), neopentylallyl barbituric acid(142), several urazole derivatives(143, 144), Ethotoin(145), Posedrin(146) and Meratran(147). Buchtal and Svensmark(148) reported some interesting studies on the relation of blood levels of Dilantin and phenobarbital to their clinical effects. Experience with parental Dilantin was presented(149). ACTH was of value in the treatment of hypsarrhythmia(150, 151, 152, 153) and in some other cases of infantile epilepsy(154). Millichap(155, 156, 157) discussed the treatment of febrile seizures and offered Pyricital as an effective agent. The additive effects of Dilantin plus several other active convulsants were discussed(158).

Dilantin was incriminated as the cause of a reversible paraparesis in a patient(159), lung changes akin to gingival hyperplasia(160) and a severe hemorrhage in a hemophiliac with gingival hyperplasia(161). Experimental Tridione nephrosis(162) and two further cases of Tridione nephrosis in humans were reported(163). Peterkin(164) listed the numerous types of skin eruptions associated with barbiturates and hydantoins. Further cases of megaloblastic anemia(70, 165-168) or aplastic anemia(169) due to anticonvulsant drugs were reported.

In regard to surgical treatment, good results were obtained in psychomotor epileptics by unilateral temporal lobectomy in: 2/3 of patients who did not have tumors(170), in 32% with bilateral temporal foci but with predominance on one side and in 10% with bilateral and about equal temporal foci(171). Epileptic foci were destroyed by

the injection into them of radio-active gold or yttrium(172); specially placed subcortical lesions were reported to help some patients with petit mal(173); treatment by pneumoencephalography was reported to produce a failure to improve in only 7 out of 31 epileptics(174).

Under the heading of miscellaneous reports might be included: (a) Murphy's paper(175) that related the basis for the adoption of 19 different saints as patrons for epileptics and (b) various studies on prognosis, *e.g.*, good with mid-temporal foci(176), when focal or temporal lobe seizures start in early childhood, when centrencephalic seizures start between the ages of 5 and 9 and when the EEG is normal(177) and better for medicinal treatment when the EEG has bilateral synchronous abnormalities, seizures start after the age of 1, and when there was not a definite organic etiology nor neurological signs(178).

PSYCHIATRIC SOCIAL WORK

DANIEL E. O'KEEFE, Ph.D.¹

During the past year the demand for psychiatric social workers continued to grow. Due to the increased tempo of research on mental health problems, there has been a clearly observed trend to recruit workers who are competent in research as well as treatment. Pilot studies and demonstrations to improve methods and techniques for treatment and rehabilitation of the mentally ill, financed by the Mental Health Projects Grants program of the National Institute of Mental Health, have been one cause for this increasing need for staff.

Also, general hospitals are developing psychiatric services which are furthering the development of integrated social service departments and expanding the need for more personnel, both medical and psychiatric social workers. It is appropriate that at this time the Medical Social Work Section, and the Psychiatric Social Work Section of the National Association of Social Workers, have collaborated in a statement on *The Practice of Social Work in Hospitals*.² It covers the services of the social service department including: social casework; social work consultation; participation in planning services and developing policies within the hospital; participation in education, training and orientation programs; research and participation in community planning. Another major segment of the publication covers the administration of the social service department.

In the schools of social work in the United States last year there were over 1,000 students being trained in psychiatric field work facilities, and the interest of students in preparing for careers in mental health has remained high. Support for training of social workers for mental health careers from the National Institute of Mental Health has now reached \$4,300,000 and is distributed among

50 schools of social work. In 10 schools support is provided for third year or doctoral training. Some experimental units are being used for training in community mental health, such as the Wellesley Human Relations Service and the Illinois Mental Health Centers with community organization orientation.

The figures of membership in the Psychiatric Social Work Section of the National Association of Social Workers have shown a remarkable spurt with over 4,000 persons now being members. One factor responsible for this trend was a change in membership requirements which now permit social workers employed in the new and pioneering types of mental health facilities to be eligible for membership. This growth in membership is further emphasized by the activity of local Sections which develop their own program interests. An important development is the improved coordination and cooperation of local Sections of psychiatric social workers and local groups of psychiatrists in planning joint activities. This development is sponsored by the American Psychiatric Association Committee on Psychiatry and Social Work and the Executive Committee of the National Psychiatric Social Work Section.

As more mental patients move out of the hospital back into community life an increasing number of community health and welfare agencies are assisting in rehabilitative efforts and psychiatric social workers are called upon to act as consultants for guidance and programing. This consultative role is being studied and several schools of social work are providing course content in this area.

A new publication³ of the National Association of Social Workers gives an overview of the activities of psychiatric social workers in direct service to patients, non-

³ Psychiatric Social Workers and Mental Health. Committee on The Role of the Psychiatric Social Worker in Mental Health, Psychiatric Social Work Section, National Association of Social Workers, 1960, \$1.00.

clinical activities and other programs including social agencies, public health organizations, residential schools and children's institutions, schools and school systems, the armed forces, correctional agencies and industry. It contains a good bibliography.

Another recent publication⁴ of the Association presents the findings of a workshop conference in which recognition is taken of the increasing involvement of social workers in group services in psychiatric settings. Both social caseworkers and social group workers participated with the goal of identifying the group elements of social work practice. This

document, too, has a series of well selected references.

The Psychiatric Social Work Section has presented annually an Institute which precedes the National Conference on Social Welfare. This past year the topic was "Current Trends in After Care of the Mentally Ill." The Institute encompassed various aspects of after care programs, such as foster home care, day hospitals and after care clinics and programs under public and private agency auspices as well as community planning for after care. It is to be hoped that the proceedings of this Institute will be published, for many interesting and worth while facts and programs were described, and the contribution of psychiatric social workers in the planning and operation of these programs was discussed.

MENTAL HEALTH IN EDUCATION

W. CARSON RYAN, PH.D., ED.D.¹

The school teacher is potentially the most important professionally trained individual in the development of mental health, says Lawrence K. Frank in a recent survey report on professional schools(1). "Next to the home and parents, the school and the teachers are in the most promising position to foster mental health in the classrooms through direct relations with the class as a group and with individual pupils." Frank adds, however, that student teachers are not receiving systematic training in the newer concepts of personality development, and are still being taught educational psychology derived primarily from animal experiments that ignored the emotional and other aspects of learning, especially symbolic learning.

Recently there has been much more emphasis on positive mental health, and here the schools have a definitely useful function. "What happens to a child in school," says Dr. R. H. Felix, in a recent reprint series from *The Personnel and Guidance Journal*, "helps to determine how he will develop, what kind of person he will be, how he will be able to meet the stress and demands of life"(2).

Dr. Felix points out that since the end of World War II school systems have become one of the largest employers of mental health personnel. "At the same time the mental health professions have been intensifying their interest in schools as a vital place to study the development of children and new ways of reaching children before they develop serious problems." In the past, he says, much of the work in school mental health was focused on the psychodynamics of the child and his teacher. But now research clues from other areas have suggested a refocusing of our concerns. "For example, recent studies of mental hospitals by social scientists have pointed out the significant effects on the patient's behavior on the total environment of the hospital. These studies suggest that we need to broaden our outlook to include, among other factors, study of the school as a social system which affects the mental health of the children. This means that we must investigate the effects on the children of such aspects of the overall school program as its organization and administration, the relationships among the total school staff (including non-teaching staff), varying perception of staff roles, and methods of staff communication. Going

¹ Chapel Hill, N. C.

even further, we need to study school and community relationships and the role of the school, as part of the larger community environment."

That instructional activities must remain the definite task of the teacher is emphasized by Bonney(3). "This means that a teacher is not a clinician, a substitute parent, a group psychotherapist, a counsellor, a test specialist, or a psychologist. It follows, then, that what teachers do to promote mental health among pupils must be those kinds of things which are intimately involved in their usual roles as teachers. Unless a teacher can help achieve mental health goals through socialization procedures, classroom management, sociodrama, class discussions, physical education activities, clubs, programs, and pupil contributions to all kinds of endeavors, then all that is left is the stimulation of intellectual growth through assignments which are prepared and 'handed in' on an individual basis. Although this is important, it falls far short of the potentialities of the school for helping our young people for the diversities of life and for the fuller satisfactions of living."

What kind of professional preparation can be provided for teachers and other educational workers if they are to perform adequately in a mental health program? Herbert A. Otto, of the University of Georgia College of Education has recently reported on efforts at his institution to meet this problem. The teacher-training program, he says, needs to help teachers and other school workers on "how to recognize symptoms, how to give basic supportive help, and how to make adequate referrals and utilize treatment resources." Programs with emphasis on the development of positive mental health, he says, are based on a recognition of the importance of the teacher as a key person in the child's emotional maturation and his character and personality development. "It is a fundamental hypothesis of such programs that if the teacher can be given an increased measure of self-understanding, some basic knowledge of personality dynamics and a grasp of funda-

mental health principles or concepts, he will be in a better position to create the type of classroom environment which will foster healthy growth"(4).

The 1960 White House Conference on Children and Youth gave considerable attention to the "emotionally handicapped." It recommended that National, State, and local governments participate in financing treatment services for emotionally disturbed children on the same basis as for other handicapped children—specifically, that facilities for prevention, detection, diagnosis be improved and extended, with provision of mental health consultation services in public schools, both rural and urban, especially in the lower grades, and that community guidance services be provided, particularly children in the early school years. The Conference also recommended that "in view of the shortage of adequate personnel and the rapidly increasing number of emotionally disturbed children, special efforts be made to attract medical students into the field of childhood emotional disturbances, by making these positions more rewarding financially and more satisfying professionally and socially; further, that the professional preparation of all people concerned with children include courses in human development and behavior, and training in the early detection of emotional disturbances and in referral methods and resources. It was also suggested that "selected youth and lay adults participate under supervision in established community programs for the mentally disturbed"(5).

PSYCHIATRIC NURSING

MARY F. LISTON, R.N.¹

There is considerable evidence that many nurses are becoming increasingly involved in the various aspects of psychiatric nursing including the promotion of mental health, the prevention of mental disorder, the treatment and curative aspects of mental illness, rehabilitation of the mentally ill and follow-up nursing care of patients after discharge from mental hospitals.

A review of the *Newsletter* of the NLN Council on Psychiatric and Mental Health Nursing indicates that state and local council members have been concerned with a wide range of activities and programs. These included the following topics: education and training of the psychiatric aide or technician; the needs of children; nurse-patient relationships; the role of the head nurse in the psychiatric setting; application of psychiatric nursing principles in general nursing practice and follow-up care for discharged psychiatric patients and their families(1).

Additional organized activities included a series of regional institutes on psychiatric nursing practice sponsored by the American Nurses' Association Conference Group on Psychiatric Nursing Practice(2), a regional workshop on inservice training in psychiatric nursing sponsored by the WICHE Mental Health and Nursing Councils(3), programs on psychiatric nursing at the APA Mental Hospitals Institute(4), at the annual meeting of the American Psychiatric Association(5), and at the biennial convention of the American Nurses' Association.

Continuing emphasis is being placed on the need for clearer definition of the role of the psychiatric nurse. The role of the staff nurse in psychiatric settings varies from situation to situation and is influenced by several factors over which the nurse may have little control(6). Peplau has stated "when mental illness is seen as a result of interpersonal and sociological influences which shape patterns of living, then the actions of the nurse in intervening in socio-

psychiatric problems must be guided by an awareness of what she is doing and by disciplined use of the work role in relation to the problem at hand"(7). Nurses and their co-workers need to examine certain patterns of staff-patient interaction which tend to perpetuate psychopathology of patients(8).

The nursing of children with special emphasis on the needs of emotionally disturbed children and retarded children is an area of increasing interest and concern. Professional nurses are playing a large part in the treatment practices and in direct care of individual and groups of emotionally disturbed children(9). A therapeutic program implemented in a boys camp setting for the treatment of neurotic children, revealed that the infirmary is suited particularly to meeting the adaptive forms of neurotic expression as those which find outlet in somatic complaints(10). Emphasis is being placed on the need to better understand the retarded child and his parents and in turn stimulate community action in the field of mental retardation(11).

Interest continues in the mental health aspects of public health nursing. The Visiting Nurse Association in Hartford, Connecticut is currently involved in a 3-year study project designed to develop and evaluate public health nursing services for mental patients and their families(12). The public health nurse is seen as playing a number of roles in mental health(13). Experience in one agency has indicated the use of group meetings led by a psychiatrist and mental health nurse consultant as a useful tool in helping staff nurses to better understand their patients(14). The development of newer programs and the involvement of public health nurses in a broader scope of mental health services raises many questions for those interested in the preparation of public health nurses as well as the continuing education of those currently employed(15).

Research in the clinical aspects of psychiatric nursing is gaining momentum. Studies have focussed on the attitudes of nurses to-

¹ National League for Nursing, 10 Columbus Circle, New York 19, N. Y.

ward various categories of activities in psychiatric nursing (16), on an operational definition of what psychiatric patients perceive as therapeutic interaction among their daily life on a psychiatric ward (17) and the use of techniques to reduce or eliminate the frequency of incontinence and to increase the incidence of the patients' socially desirable habits in a psychiatric ward setting (18).

Nursing educators have been involved in numerous activities related to undergraduate and graduate nursing education. Continuing study is being given to the problem of integration of psychiatric nursing concepts throughout the basic nursing curriculum (19). Educators are concerned with the application of the principles of behavior in all clinical nursing situations (20). The inadequate recruitment of nursing students for psychiatric nursing has indicated the need for a critical examination and reappraisal of the content and learning experience currently offered in the basic course in psychiatric nursing (21).

A small group of nursing faculty members from graduate nursing programs in the western region participated in a seminar group to define the clinical content for graduate programs in psychiatric nursing (22).

Problems in aide education including the selection and training of the psychiatric technician (23), the desirability of periodic reassignment of aides to various shifts (24), the aides' role in remotivation (25) and the use of special techniques in psychiatric aide inservice training are areas of current interest. The NLN Seminar Project for Teachers of Psychiatric Aides has completed a series of seminars in Arkansas, North Carolina, South Carolina and Tennessee (26). Articles written by aides for *The Correspondent* indicate considerable interest and enthusiasm for the therapeutic aspects of the aides' role in working with patients (27).

While much has been accomplished, there is need for continuing interest, initiative and support in the study of such problems as the improvement of learning experiences in psychiatric nursing for undergraduate

and graduate students, definition of the role of the psychiatric nurse in community mental health facilities, i.e., day and night hospitals and mental health clinics, and increased recruitment of nurses for psychiatric nursing.

FAMILY CARE AND OUTPATIENT PSYCHIATRY

WALTER E. BARTON, M.D., AND WILLIAM T. ST. JOHN, M.D.¹

FAMILY CARE

The number of Family Care placements in the United States increased during 1960.

TABLE 1

Patients in Family Care in the United States
as of June 30, 1960

	ALL PATIENTS	MENTALLY ILL ONLY
New York	2,875	1,940
California	1,558	999
Michigan	1,205	855
Illinois	1,179	931
Ohio	1,061	1,061
Maryland	497	497
Pennsylvania	418	418
Kansas	394	394
Rhode Island	277	277
Massachusetts	467	216
Idaho	33	33
Florida	29	29
Virginia	14	14
Veterans Administration (January to December, 1959)	2,500	1,946
Total	12,507	9,610
Texas (convalescent leave)	1,039	
1959	10,816	6,854

Pennsylvania reported a substantial decrease due to a change in the method of statistical reporting, and the fact that they are now using the definition of Family Care required by the National Institute of Mental Health. Texas reported 1,039 patients on Family Care convalescent leave. It is doubtful whether the use of Family Care in that state conforms to that in common usage elsewhere.

Hester B. Crutcher reported a marked increase in requests for Family Care placements from both patients and staff of hospitals where most of the wards are opened.

¹ Superintendent, and Assistant Superintendent, Boston State Hospital, Boston, Mass.

The patients in open ward hospital settings are given more freedom than they formerly had, and are encouraged to assume increasing responsibility for the planning of their own time and activities(1).

The Veterans Administration reported 1,300 patients discharged to the community from Family Care during the past 5 years. They also note:

(a) During this period, patients with a residence in the hospital of 10 or more years increased to 36% of the total placements, and

(b) a steady increase occurred in the placement of patients in the 40 to 50 year old group(2).

Giovanni and Ullman found that men who were comparatively unsuccessful in first Family Care placements may well have more favorable outcomes when replaced. The best single indication for replacement is a history of a relatively long stay in the family care home. A "relatively long" first placement, according to the authors, amounts to 4 or more months.

If a person has been in the hospital more than 10 years, the authors state, success in Family Care is more likely to follow than in those cases where the hospital residence was short(3).

In Uppsala, Sweden, Dr. Wahlström and his staff of two doctors and three nurses care for 300 patients in Family Care. The homes are located in rural areas and a single home may care for as many as 25 patients. The amount of money paid to each family varies, with the degree of illness; patients who are sicker are paid for at higher rates and tend to be in the larger homes.

In Beilen, Holland, an outstanding family care program utilizes an inpatient admission center as a day hospital for those patients placed in the community. Patients in foster homes report each morning for therapy and

return home at night. This program has several advantages :

(a) Intensive treatment makes possible the placement of patients who are still quite sick.

(b) Rehabilitation is easier to accomplish.

(c) More adequate supervision is possible than is customary in a family care program.

(d) The inpatient admission center is able to supervise more patients in active therapy without expansion of bed capacity

(4).

Several states reported the use of radio and TV—in some, closed circuit TV—as a public education service to explain the advantages of Family Care.

The *Family Caretaker's Clarion*, a periodical published by the caretakers of Family Care homes in California, provides a medium of education and communication on a state wide basis. The interest aroused by the news sheet has also served to publicize the program and to recruit additional Family Care homes.

OUTPATIENT PSYCHIATRY

At the 116th annual meeting of the American Psychiatric Association, Moore, Albert, Manning, and Glasser reported that prior to a community extension service set up to study and develop alternatives in hospitalization, 80% of the patients on the waiting list at the hospital became inpatients within 90 days. The remaining 20% received outpatient care or refused all treatment. With the advent of the community extension service, only 40% of the patients were admitted as inpatients; full time hospitalization, therefore, was circumvented for 60% of the people for at least one year. Of the 60%, 18% were treated in a day hospital and 42% were treated without institutional care of any kind(1).

Robinson, de Marche, and Wagle in their investigation of the community resources in mental health indicate that Outpatient Clinics are concentrated in the northeast area and north central states. Very few counties in the rest of the country had such services. In the southern states 87.9% of the counties lacked clinics, and in the mountain and Pacific areas 82.9% of the counties

were without such service. Counties without mental health clinics usually lacked other supportive services as well. The areas that did have clinics were concerned about the small number of patients seen. Often there was a waiting period of 2 months for diagnosis and 5 months for treatment. The community tended to resent waiting for service and this reacted unfavorably. Objections tended to develop in the referring agencies such as the courts, schools and private professional groups. The lack of coordination among the facilities available for different types of diagnosis and treatment was evident. Often a patient would be evaluated in one center and would be referred to another center for treatment where the diagnostic process was repeated. The authors emphasized the need for a community "all purpose agency" that would be not only a diagnostic center but also a referral agency. Too few clinics currently exist. The United States Public Health Service, on the basis of the 1954-1955 data, reported that there were 1,234 outpatient psychiatric clinics in the United States. (Bahn and Norman, 1957.) They estimate the need for one clinic for every 50,000 people(2).

The deficit in outpatient clinics is partly due to the lack of full time psychiatrists. Worley's survey indicated that the largest number of psychiatrists employed by outpatient clinics work on a part-time basis. They come from the inpatient psychiatric staff, private practice, the teaching profession, research, and the consultant fields(3).

Coleman emphasizes the need for around-the-clock outpatient service without appointments to allow the patients and their families to feel more comfortable because of the availability of help whenever it is needed. Twenty-four hour service has proven to be a way of preventing hospitalization for some, as well as a way of screening others during their period of emotional crisis, to allow them to get into proper treatment. In addition, it frees the city hospital wards from their useless and demoralizing task of being way stations on the path to a state mental hospital(4).

Lowinger and Gottlieb bring out the changes in management of the schizophrenic patient. With many schizophrenics now living in the community, and with the

use of more drugs in their treatment, the development of a drug clinic as the hospital's outpatient facility was initiated. Here various drugs can be used and reviewed with the patients returning at frequent intervals for regulation of medication depending upon their responses and their needs. More patients can be cared for in less time with this arrangement of the clinic(5).

An outstanding contribution during the past year was "A Guide to Communities in the Establishment and Operation of Psychiatric Clinics." It provides essential information about the organization, staffing, administration of psychiatric clinics, and the clinical and related educational and consultant services in local American communities(6).

Casey, Rackow and Sperry, in "Observations on the Treatment of the Mentally Ill in Europe," found psychiatrists, social workers and psychologists working as a team in outpatient clinics as they do in America. The outpatient clinics served to screen new cases. Individuals who have developed emotional illnesses go to the outpatient clinic for examination and evaluation. Where possible, they are treated in the outpatient setting in the hope that it will not be necessary for them to be sent to the hospital. However, if hospitalization is necessary, a preliminary diagnostic work-up is completed. Therapy, in the outpatient clinic, includes a moderate use of tranquilizing drugs. Great Britain's outpatient clinics are staffed by the psychiatrists on the staff of the local mental hospital. One physician may serve in a number of different clinics(7).

FORENSIC PSYCHIATRY

WINFRED OVERHOLSER, M.D., Sc.D.¹

As usual, the periodical literature lays stress on the criminal aspects of forensic psychiatry. One of the most discussed cases is that of *Regina v. Podola*, an English murder trial in which amnesia was unsuccessfully pleaded in bar of trial rather than as a defense to the charge. Hargrove(1) suggests that the defendant could well have been confined in Broadmoor for study and treatment rather than being rushed to execution. Gooderson(2) is likewise critical of the way the case was handled.

Considerable attention is given, particularly in England, to the recent (1957) Homicide Act recognizing "diminished responsibility" as a defense. Neustatter(3) suggests that the defense should not merely shorten the sentence. Maddison(4) denies that there is a sound basis for the theory that a man is either accountable or unaccountable. Williams(5) discusses a recent English case in which it was held that the judge may guide the jury in interpreting the statute. Lord Keith(6) points out that the new law modifies the conception that there is no "halfway house" between complete legal irresponsibility and the understanding of a reasonable man. Starnes(7) notes that New Mexico in a recent case has recognized partial criminal responsibility. Lady Wooton(8) reviews recent experience with the Homicide Act, and looks on the concept as an attempt to "escape from the shackles of a penalty rigidly fixed by statute." She hopes that ultimately the whole concept of responsibility will "wither away," permitting the psychiatrist to cease his "masquerade as a moralist."

An anonymous note in the *Stanford Law Review*(9) discusses a recent California case (*People v. Gorshen*); the writer calls for a reappraisal of the M'Naghten Rule

and of the awkward bifurcated procedure of California in cases in which insanity is pleaded as a defense. McEntee(10) discusses a recent New Jersey case (*State v. Lucas*) in which the M'Naghten Rule is reaffirmed.

Interest in the New Hampshire and Durham Rules continues. Reid(11) contributes a full and scholarly study of the evolution of the New Hampshire Rule as enunciated by Judge Doe. Clayton(12) studies the operation of the Durham Rule and concludes that "society will benefit most by sending more criminals to hospitals and fewer to prisons."

Perret(13) discusses the contributions of psychoanalysis to medico-legal examinations, both in understanding unconscious motivations and in aiding in the offender's rehabilitation.

Augle(14) reviews the care and treatment of psychopathic offenders in Scandinavia, with reference to institutions. Tasher(15) discusses a treatment program in a maximum security hospital. Wilson(16) describes the functioning of a psychiatrist in a law enforcement agency. He urges further use of the psychiatrist by police departments. McKendree(17) discusses the procedure for the evaluation and release of "dangerous" patients. He concludes that the patient on convalescent status is less of a menace to the community than a nonhospitalized member of society.

An excellent review of sexual psychopath statutes is given by Swanson(18). He is critical of the statutes as lacking objective standards and as (in some cases at least) being violative of civil rights.

Nyirö(19) discusses the impaired judgment of the senile as affecting criminal responsibility.

Slovenko(20) considers the question of medical privilege and its relation to the

¹ Professor Emeritus, George Washington University, School of Medicine, Washington, D. C.

work of the psychiatrist. He points out as an anomaly the fact that in three states the psychologist has statutory privilege, whereas the physician has none! The question of privilege is discussed at length in Report 45 of the Group for the Advancement of Psychiatry(21).

Modjeska(22) deals with the legal concept of delusion (in will cases) as exemplified in a recent Wisconsin case (Will of Riemer). The court seems to have adopted a more psychiatric viewpoint than formerly in determining the effect of delusion on testamentary capacity.

Lebensohn(23) attacks the cumbersome and expensive provisions of the District of Columbia law for the commitment of the mentally ill. His criticisms are applicable to a wider circle of jurisdictions than the District only!

Several symposia may be mentioned—the Ohio State Law Journal(24) (Weihsfen, Lasswell, Kittrie, Rita James, Ralph Patterson, *inter alia*); Law and Contemporary Problems on Sex offenses(25) (Ploscowe, Glueck Sr., Bowman and Engle, J. E. H. Williams, Sturup) and Cleveland and Marshall Law Review(26) (Szasz, Crawfis, Davidson and Perr, to mention a few contributors).

As for books, one should mention David Abrahamsen's *Psychology of Crime*(27).

Very few legislatures were in session, and the grist was slight. Georgia(28) transferred the Milledgeville State Hospital to the State Board of Health. Wisconsin(29), for no very clear reason, prohibited the issuance for one year of a motor vehicle operator's license to persons convicted of a sex offense—a curious penalty imposed on a special class of offenders!

ADMINISTRATIVE PSYCHIATRY

J. MARTIN MYERS, M.D., AND LAUREN H. SMITH, M.D.¹

Administrative psychiatrists, constantly preoccupied with the desire to learn new and more effective ways to treat psychiatric illness, have been studying the programs developed in many other countries. They have been experimenting with modifications of these programs in this country as well as assessing the value and cost of their own. The limitation to two loci for patient treatment, either as a full-time resident in a mental hospital or in the psychiatrist's office while living at home, has given way to many modifications of treatment facilities for greater adaptability to the patient's needs. A great deal has been learned from England where the National Health Service has provided for a unification of psychiatric service which brings in general practitioners and public health authorities to the treatment program. The mental hospital has been the hub of these developments with the hospital psychiatrists going out for home visits, running clinics in the general hospital, and operating day centers(1, 2, 3, 4). The new English Mental Health Bill (1959), which provides a single code covering both mental illness and mental deficiency, will undoubtedly raise the already high percentage of voluntary patients in their hospitals and increase the movement of patients in and out of the various psychiatric treatment facilities(5, 6). In the Soviet Republic visitors indicate that the psychiatric dispensary in the community rather than the hospital is the nucleus for psychiatric treatment. That the hospitals of Russia are generally better staffed than those in the U.S.A. is only one of the interesting observations made by Kalinowsky(7) and Kline(8).

At the Hudson River State Hospital, a special sub-hospital has been created for direct admission of patients from Dutchess County, New York. It has its own day care center(9). Louisiana outpatient centers were set up at strategic points in the area served by a state hospital with a resultant

great saving (75%) of hospital admissions (10). Others report success with emergency psychiatric service prior to admission(11, 12, 13). Careful studies at the Butler Mental Health Center show that the community can save money by utilizing any of several types of active treatment, including long individual psychotherapy, instead of hospitalization(14, 15).

For years many authorities have stated that psychiatric hospitals should be kept small and not overcrowded. A VA hospital study shows that smaller hospitals release patients earlier than large ones regardless of whether the staff/patient ratio is high or low(16). A method for breaking large hospitals into small units of 250 patients has been described(17); actually a somewhat similar procedure to this is the prevalent one in France, the separate units being given separate names. At the Philadelphia General Hospital, two periods before and after an administrative decision to limit admissions to bed capacity were compared: under the more adequate conditions, not only were as many different patients treated but the number of readmissions was reduced, the length of stay shortened, and the number of patients committed to a state mental hospital decreased(18).

Epidemiological studies on the incidence of mental illness in the U.S.A. have been reviewed with comment by Plunkett and Gordon(19). British statistics generally confirm American ones(20). Other reports are from Thailand(21), South Pacific(22, 23), and Norway(24). It appears that local factors concerning availability and type of psychiatric service are most important factors in determining the number of admissions. Christe, reporting on the increase in admissions (5½ times), decrease in length of hospital stay (½ times), and increase in readmissions (10 times) between 1917 and 1956 at the University of Basle, recommends that the neurotic depression be treated in general hospitals, that autonomous open pavilions, old age homes with locked units, and special alcoholic divisions be developed(25). It

¹ Pennsylvania Hospital, 111 N. 49th St., Philadelphia 39, Pa.

is suggested from Sweden that mental hospitals of the future be planned on the basis of 5 beds per 1,000 population (26).

Continued experience with the day hospital and day-night hospital is being published (27, 28, 29, 30, 31, 32), as well as that of psychiatric units in a general hospital (33). For those planning on developing the latter, a section in *The Modern Hospital* would be worthwhile reading (34). Adolescent units are described as they have functioned in a psychiatric hospital (Bellevue) (35) and in a general hospital (Michael Reese) (36).

Work with pay in industrial projects for hospitalized psychiatric patients seems to be increasing. Reports have been published recently from England (37), the VA (38), and Manhattan State Hospital (39, 40). Two psychiatrists and one architect authored the World Health Organization publication "Psychiatric Services and Architecture" (41). It considers outpatient clinics, early treatment centers, day hospitals, psychiatric hospitals, after-care homes, and sheltered workshops. Consideration is given to the design of mother-baby units in the mental hospital.

It is not possible to review the many articles dealing with the interaction of staff attitudes and patient welfare and improvement, the problems of administrative functioning and communication, the relationship with the community. Recently a review of the literature titled "The Mental Hospital and the Treatment-Field" has been published covering literally many hundreds of articles and books published over the years (42).

Administration of the Public Psychiatric Hospital is the subject of GAP Report #46 (43). Many of the administrative problems found in small non-governmental supported hospitals are discussed in the *NAPPH News Letter* (44).

MILITARY PSYCHIATRY

JOSEPH S. SKOBBA, M.D.¹

Increasing recognition and investigation of new stresses arising out of changes and new developments in military practice have prompted a re-evaluation of training programs for military personnel.

The experiences of Korean prisoners of war led Wolff(1) to examine the historical records of the prisoners of war in the light of scientific knowledge regarding human reaction and environmental stress with particular attention to interrogation. He submits the following recommendations to officers concerned with "Code of Conduct" training problems :

That the military training and discipline be directed so that individuals may be identified with military groups in which there is an unbroken chain of command to the end that officers be unquestionably trusted and obeyed even when a captor discredits or attempts to undermine authority ;

That the futility and genuine hazards of collaboration with the enemy be emphasized ; there should be no doubt as to what is collaboration and what is proper conduct ;

That it be insured that all military personnel know what to expect as a prisoner of war and what is expected of a prisoner of war by his own people in the way of resisting collaboration.

Furthermore, Wolff urges continued support and encouragement to the prisoner from the home government. All steps should be taken to communicate, such as mail

service, food drops, and dropping of inspirational leaflets. The civilian community must instill in the individual, prior to military service, the need for commitment and the determination that a committed man's loyalty has no breaking point.

Kinsey(2) considers that new stresses have been added to submarine duty by the feasibility of prolonged submersion and the development of new weapons. These stresses are expected to increase. Operating personnel are faced with a contracting environment. There is a decrease in sensory input principally due to lack of variety of stimuli ; energy output is reduced, and long periods of isolation characterized by long periods of repetitious activity are experienced. These conditions demand refinements in assessment and selection of personnel for this type of duty. He describes an experiment for determining motivational factors involved in volunteering for unusual or hazardous duty. There is a need for tests to measure the duration of motivation which could be applied periodically. He recommends that training be extended to meet the new and more prolonged stressful conditions likely to be encountered in the future. Mention is made of one program along this line using a two team concept.

Rand(3), an artillery officer, wrote about the conditioning of the soldier for nuclear war. While this article is directed to those concerned with the training of the soldier, it informs us that line officers are fully aware of the psychological aspects of nuclear warfare and are working out their own solutions in the direction of preventive psy-

¹ 132 Doctors Bldg., 490 Peachtree St., N.E., Atlanta 8, Ga.

chiatry. He noted that there is a paucity of information concerning the psychological impact of nuclear weapons on human beings who operate on the battle field. Likewise there is little known of the effect on the commander and on his decisions pertinent to the reaction of his men to this new type of warfare. He maintained that at present there exists a deep nation-wide apprehension which is also possessed by military personnel. He proposes that training should prepare the individual to accept greater stress and to sacrifice all if necessary. Because of the loss of mutual support under nuclear battlefield dispersion, he emphasizes that training be directed towards greater development of individual confidence, initiative and self-reliance since the soldier must become accustomed to being isolated in battle.

Ruff(4) discusses crew selection for space flight. Until such time as actual manned space flights are made, he proposes that the nature of the stress expected to be encountered should be studied under conditions simulating space flight. The selection and predictions should be made on the basis of current methods of evaluating mental stability and tested in laboratory stress experiments. As data concerning stress and behavior in actual space missions becomes available, the tentative criteria can be more explicitly defined and more objective measures employed.

Kolmer and Lysak(5) studied a sample of 100 trainees who were given a profile rating of S-2 and S-3. These refer to neuropsychiatric status or degree of emotional stability indicating mild(2) and moderate(3) defect.

In a follow-up shortly after induction and again early in the basic training cycle they found that 80% had too high an S rating. It was their opinion that this high rating called the attention of the commanding officers to the psychiatric abnormalities and implied a need for modification of training demands. This was considered to be detrimental to the inductee. It was their conclusion that an accepted inductee stands a better than 9-1 chance of completing his basic training. They found that the induction station physicians evaluated the present potential for effective duty with diminished regard for

previous psychiatric disability.

Roff(6) correlated histories of individuals dealt with in child guidance clinics during their grammar and high school years with their military adaptation. He found that a history of earlier peer group difficulties tended to identify subsequent neurotic deviation in the service. In a second phase of the study it was evident that some types of diagnostic-predictive comment were not discriminative with respect to subsequent service adaptation. However, when clear-cut diagnostic evaluations had been made, the long time predictability was substantial.

Marshall(7) describes a testing program carried out in the field over a period of 20 months. The testing was done by clinical psychology specialists under the supervision of a clinical psychology officer. The administration of the tests was done in the unit area in whatever space was available such as day rooms, quarters, or any spot providing privacy. Reasons for referral were evaluation of intelligence, evaluation because of poor performance, and evaluation of personality. A Standard battery of psychological tests, including projection tests, was used. The results were submitted to the Social Service section for evaluation and forwarding to the psychiatrist if considered indicated. The objective was to provide a finer screening process in the unit before psychiatric referral, to provide the psychiatrist with a report before the individual was seen by him, to offer assistance to the Social Work Section in understanding the soldier, to minimize the loss of training time, to avoid removing a soldier from his unit and to prevent the development of the patient role and a self concept detrimental to his functioning as a soldier. The effectiveness of the program was shown by the fact that of the 27 patients recommended for duty without referral to the psychiatrist, none was discharged or came to subsequent psychiatric attention while at the basic training center.

Kramer and Young(8) describe a situation where a psychiatrist was assigned as a probation officer. The clinical record is given in detail. They found that the diverging responsibilities of the probation officer and the psychiatrist—the former to the court, the latter to the patient—made it diffi-

cult to render completely satisfactory service to either party. They considered the dual relationship a serious limitation to the employment of a psychiatrist as a probation officer. They conclude that where psychiatric treatment is indicated, the psychiatrist should act in a strictly professional capacity and another officer should be assigned as probation officer.

Hillbom(9) studied more than 3,000 soldiers with brain injuries from among the soldiers of Finland who incurred their injuries during the wars of 1939-1940 and 1941-1944. He selected 415 cases in a statistically valid manner for detailed evaluation. He had been of the opinion that ratings of disability were either too high or too low because of a lack of information on the course of brain injuries. One section deals with the psychiatric aspects. Of interest is his opinion that the neuroses following trauma are not compensation-striving but a sequel to the stress of the handicap and also of interest is his statement that there is not a single case of "so-called genuine schizophrenia" in his case material. This study is available in English.

This year there has been the largest number of listings of references in foreign languages that has occurred in the Index Medicus in recent years(10).

PSYCHIATRIC EDUCATION

FRANKLIN G. EBAUGH, M.D.,¹ AND ROBERT H. BARNES, M.D.²

In medical education circles concern with the sobering facts of student and personnel shortages continue to plague our current activities and obscure future planning. Ward Darley(1) predicted an annual deficit of 3,000 physicians in 15 years unless major expansions in medical schools are undertaken. A comprehensive study of this problem was reviewed by a U. S. Public Health Service officer(2), who suggested that to keep our present physician-to-population ratio, we will have to increase our output from medical schools by 50%. To further worsen the picture, many observers

question whether our society, with greater numbers of old people, an ever increasing standard of living and new and complicated medical advances, will accept *merely* a holding of the physician-population ratio constant. Yet to *merely* hold the ratio constant will take *very* major expansions of training facilities, and to do more will require a "crash program" of unheard of proportions in the next decade. How complex a problem any expansion of medical school output will be is underlined by the fact that for the third year in a row the number of applicants for medical schools decreased (this year about 3% over last year)(3). The Director(4) of the Office of Scientific Per-

¹ 1801 High St., Denver, Colo.

² Kansas City, Mo.

sonnel of the National Academy of Sciences noted the stiffly competitive field we find ourselves in when searching for "high talent." As he points out, the solution is much more than improved recruitment of college students and must involve changes in our whole educational system, beginning at the grammar school level.

It appears obvious that only as we can solve the general problem of medical manpower shortages do we have any possibility of significantly altering pressing shortages of psychiatrists. In 1958 the Council of the American Psychiatric Association authorized a manpower study project. This is well begun and tackling: 1. Analysis of the existing psychiatric manpower picture and 2. Techniques of increasing the supply of psychiatrists(5). We are in a period where frequent comparisons of ourselves with Russia occur. Kalinowsky(6), in a recent review of Soviet Psychiatry, estimates there are more psychiatrists per unit of population in Russia than in the United States. He notes that the majority of their medical graduates are women and that their medical school output approaches 20,000 per year (compared with 7,000 per year in the United States).

UNDERGRADUATE PSYCHIATRIC TRAINING

Lief and his associates at Tulane(7) have presented an interim report on a highly significant 6 year project studying the adaptational problems of medical students in relation to their personality dynamics. Hopefully this study will lead to better criteria for medical student selection, as well as training programs to produce "the best fit between personality of medical students and the types of learning experience to which they are exposed." Tyler(8) indicates the abysmally inadequate background of pre-medical students in the basic psychological and social sciences. Paradoxically little is done in the first two years of medical school to rectify this. Tyler's studies of 81 medical schools indicate that less than 4% of clock hours in those years are spent on material in the broad field of human behavior. Our greatest gains in placing behavioral material in the curriculum for medical students has been in the third and fourth years--the clinical years, learning

basic behavioral data in a grossly neglected state. Another author(9) reviewed the manner in which basic psychology--"the science of the behavior of living animals"--is taught in the second year of medical school in New Zealand, and by medical psychologists. Jaco(10) further emphasized the need for extensive social science teaching in the medical school and believes this will lead to the establishment of autonomous departments of behavioral and cultural medicine within medical schools. A model for this type of development is seen at the University of Kentucky with its new Department of Behavioral Science. At Duke an interdisciplinary approach to basic behavioral science teaching has been carried on for 7 years. Cohen(11), in describing this 72 hour lecture and laboratory course, notes that it has been alone effectively *without* a separate behavioral science department.

The amount of current literature describing teaching programs aimed toward the assimilation of a "comprehensive" view of clinical medicine by the student has fallen off markedly in 1960. However a very significant book-length summary report of the Commonwealth Fund supported project at the University of Colorado appeared(12). This compares the results of the more classic teaching of medicine in the outpatient departments of Colorado General Hospital with those of teaching medicine "comprehensively" in the clinics of nearby Denver General Hospital.

Several interesting studies of teaching techniques for medical school psychiatry appeared. At the new University of Florida School of Medicine(13) role playing techniques were found highly effective for large medical school classes. They appeared much more useful than films because of the high degree of peer involvement. Stunkard(14) also found role playing techniques useful for elucidating clinical problems, particularly those involving doctor-patient interactions. Interview and diagnostic processes were well followed by this type of presentation. Werkman(15) used role playing techniques in teaching the interpretive process to medical students. Cases worked up in a children's psychiatric service were reviewed by students and staff, and the students were prepared for interpretation of the results to

the parents of the clinic children. The preparation was largely through role playing demonstrations and the students began to find answers to such questions as, "How do I tell this mother that her little boy has unmet emotional needs?" A group at the University of Kansas Medical School(16) describe 4 years experience with the use of closed channel television (black and white), in teaching psychiatry, particularly to medical students. Up to 100 students viewed interviewing and other demonstrations with the maintenance of a high interest level. It was felt this was a valuable tool for psychiatric teaching—"simple, cheap, reliable, convenient and efficient."

GRADUATE TRAINING

Latest available figures(17) on psychiatric residency programs indicate there are 303 programs in existence (last year 288), with 3,009 appointees (last year 2,770) and 649 vacancies. This gives an occupancy rate of 82% (last year 78%), compared with 87% for all residency in all specialties in the U. S.

Foreign medical school graduates continue to occupy an important place in our training programs with 6,720 present in the U. S. in all residencies (24% of residents). In psychiatry there are currently 566 foreign medical graduates, giving us 19%—or a somewhat lower percentage than for non-psychiatric residencies. The Educational Council for Foreign Medical Graduates reports(18) that as of August 15, 1960, they have evaluated the credentials of over 20,000 foreign trained physicians seeking internships and residencies here. Twelve thousand and eleven had taken the examination with 62.2% qualifying with scores of 70 or above. Slightly under 40% qualified for a standard certificate with scores of 75 or above. The American Hospital Association has held December 31, 1960, as the final date for compliance with their order to clear hospital rosters of uncertified foreign medical graduates or lose their accreditation by the Joint Commission(17). This will pose many individual problems and for certain selected hospitals a very heavy immediate burden. However there has been general acceptance of this move as necessary to maintain reasonable quality of

trainees and training programs. That it constitutes a major problem to any of our hospitals and training programs, underlines in another way our basic shortages in medical student production.

Goshen(19) in an excellent and critical review of psychiatric training takes a most pessimistic view of our field, pointing out that the demand for psychiatric services is increasing exponentially—due to increasing prosperity and sophistication of people as well as population growth—while we are not increasing our production of psychiatrists very greatly. He believes that we must meet this challenge or else the science of human behavior will be taken over by more vigorous groups. He places the main burden on the medical schools and psychiatric education therein. Jacques Barzun(20) puts his finger on one of the major problems in present day American academic life—and this includes psychiatry: our modern attitude toward research, which he compares to the medieval attitude toward pilgrimages. He feels that the influx of research money has resulted in institutions that are primarily educational placing a higher premium on research than on good pedagogy. He notes the contempt that many professional teachers have for teaching *per se*, with their advancement academically dependent on research productivity rather than teaching capability. In this regard Kalinowsky's(6) observation that training and research are generally separate in Russia, with independent psychiatric research institutes being the rule, is of more than passing interest.

The Johns Hopkins group(21) have continued their studies on the relation between the therapist's (psychiatric resident) attitudes and personality attributes and his effectiveness with schizophrenic patients. This is an article of very great significance to everyone engaged in the business of selecting and training psychiatric residents. Another interesting study on the effects of the physician's attitudes on outcome of treatment is described by Haefner, *et al.*(22), in an article entitled, "Physician Attitudes toward Chemotherapy as a Factor in Psychiatric Patient's Response to Medication." Bailey(23) chides us for our "schizoid" attitudes toward brain and behavior and

urges us to weave biological data—"so rapidly accumulating"—more intimately into our psychiatric teaching and cease to teach our "neophytes in terms of mythological pseudoscientific pseudoentities."

The importance of the psychiatric resident learning to deal with both the patient and the patient's family is emphasized by the Syracuse group(24). This would appear to be part of his training experience, to be covered in the resident's supervision as well. A Maryland program(25) indicates a method for cultivating community mental health leadership through placement of third year residents in the role of consultants to local health departments and as directors of part-time mental health clinics. Training of residents in this type of activity, including work with the various other "gate-keepers," learning the techniques of good consultation may be our most useful contributions at present to the preventative field. Certainly the most recent definitive report on other aspects of mental health education(26) indicates the general lack of agreement as to values, goals and techniques.

Rosenbaum(27) presents the difficulties in teaching psychosomatic medicine, remarking that the best teaching is done when the resident has full responsibility for continuous management of the patient and is supervised by a teacher—whether psychiatrist or internist—who is engaged personally and currently in long-term patient care. As he points out, this means well qualified psychosomatic teachers are rare indeed. Laughlin(28) has recently reviewed European psychiatry and remarks on training in English medical schools. Apparently undergraduate psychiatric training there is minimal and few graduates become interested in this specialty. Part of this may be related to slow evolution and strong traditions, making advances in a new field difficult. Lack of money appears to play a role also, England not having had the great impetus to psychiatric education which has come in the U. S. from extensive federal support of training and research.

In February, 1959, the American Board of Psychiatry and Neurology gave formal recognition to Child Psychiatry as a subspecialty in Psychiatry. Allen(29) has reviewed the developments in the field lead-

ing up to this. Robinson(30) gives special emphasis to the unique training developments in the field and their impact on psychiatric training in general. Harris(31) indicates there is a shift in the emphasis in child psychiatric training with more concern being given to the child with learning difficulties. This suggests the need for more extensive work with the mentally retarded child by training clinics.

Szasz(32) raises some searching questions concerning contemporary psychoanalytic training, including the responsibility of the training analyst to the candidate and to the institute. A review(33) appeared from Columbia University outlining the development of and advantages of having a psychoanalytic training unit part of a medical school and university structure.

The future of *post-graduate* medical education is apparently promising. As one author(34) puts it, "the focus in the future will be on truly high quality continuing education in which basically well-educated physicians will be attracted to participate as regularly and as matter-of-factly as they now trade their automobiles." There is a recent listing of all post-graduate courses, including those in psychiatry (a national total for psychiatry of 67)(35). These range from "Contemporary Plays and Morals in the Light of Modern Psychoanalysis," to "Psychopathology for the General Practitioner." The problem of post-graduate training in hypnosis—for psychiatrist and particularly non-psychiatrists—is dealt with by Rosen(36), who is highly critical of the barn-storming, hotel room groups currently on tour. Monroe(37) outlines a pioneer effort (at Tulane) to develop a curriculum for training in hypnosis. While currently this is designed for senior medical students, hopefully it will give ideas and experience applicable to adequate and structural graduate and post-graduate training programs in hypnosis.

REHABILITATION AND OCCUPATIONAL THERAPY

FRANKLIN S. DuBOIS, M.D.¹

During 1960 an unprecedented amount of information about psychiatric rehabilitation has been published. A survey of this vast amount of material leads to certain conclusions : 1. There have been no dramatic, new techniques of rehabilitation developed during the past year ; 2. Not only psychiatrists (1-3), but other individuals(4) and agencies(5, 6) now recognize that emotional and mental disturbances are the most extensive health problems of all and are making efforts to assist in their resolution ; 3. Rehabilitation can no longer be considered

to be just the process of readjusting the mental patient to his optimum role in society after active treatment has been completed(7), but rather a part of total therapy which includes preventive, remedial and restorative measures(8-11) ; 4. There is strong movement toward the development of community facilities in mental health care(12-38) ; 5. The traditional pattern of operation and function of the mental hospital is changing rapidly(39-41) ; 6. Greater concern is being evidenced for the chronic, long-term psychiatric patient(42) ; 7. Work programs(43-47), sheltered workshops(48-50), vocational rehabilitation projects(51),

¹ Silver Hill, Valley Rd., New Canaan, Conn.

facilities for recreation(52) and ancillary methods of treatment(53-62) are increasingly recognized as important; 8. Special attention is being paid to the elderly(63-71) and to the young(72-75); 9. Close follow-up and counseling of discharged patients are now accepted as essential for recovery(76-79); 10. Emotional factors that hamper restoration of the physically ill are being studied, understood and dealt with more widely(80-85); 11. It is more apparent that rehabilitation must be individual rather than group oriented(86, 87); 12. Research in rehabilitation is being pursued more actively than ever before(88-91); 13. More conferences on the subject are being held(92-95); 14. Psychiatry in parts of the world other than the United States is offering much that is worthy in terms of rehabilitation(96-107); 15. A markedly increased number of books on all phases of rehabilitation(108-115) and occupational therapy(116-125) has become available; and 16. Occupational therapy has continued to make progress(126-148). Obviously, it is impossible to review each of the above cited publications. Only a few of the seemingly more important ones can be considered.

Even though no dramatic, new techniques of rehabilitation have been introduced during the past year, psychiatry is making real progress in its fight against mental illness. The number of patients in American mental hospitals decreased during 1959 for the fourth consecutive year even though admissions increased(149). These and other facts about mental health have been made available in a brochure published by the National Committee Against Mental Illness(150). Such authoritative figures support the statement of Dubois(1) that emotional and mental disturbances are the most extensive health problem of all and represent a challenge to every practicing physician. Terhune(2) says this challenge must be met not just by psychiatrists but by all physicians. The United States Government holds a similar belief as evidenced by the fact that the National Institute of Mental Health(3) is sponsoring courses in the psychiatric aspects of medicine for general practitioners and the U. S. Public Health Service(5) is formulating

long-term plans for increasing mental health facilities.

Kissen and Carmichael(9) review the subject of psychiatric rehabilitation. Their report includes important statistics, significant legislation and an excellent bibliography.

Simon(10) points out that the concept of psychiatric rehabilitation has broadened markedly during the last decade. He says that it is currently characterized by 4 trends: (a) "The therapeutic use of self"; (b) The "open hospital" and "therapeutic community" and their effect on hospital-community relationship; (c) The development of a variety of transitional agencies between the hospital and the community; and (d) The establishment of the mental hospital as a true "community hospital." Ebaugh(12) is pleased with these trends and advocates that community participation in mental health be enlarged and accelerated. Rockmore(13) says that careful planning is essential if such a program is to be successful. Such planning must include consideration of: the psychodynamics of the patient's problem(Unterberger, 14); arrangements for rehabilitation as early as possible in the patient's hospital stay(Bellak and Black, 15); the discharged patient's specific needs(Kasprowicz, 17); social factors(Kris, 18 and Walz, 19); and proper indoctrination and use of the family(Evans and Bullard, 20), the home(Friedman, Rolfe and Perry, 21) and foster homes(22). Linden, Appel, Davis and Matthews(23) discuss elements influencing the success of a public mental health program; Bloomberg(24) proposes a community-based hospital as a branch of a state hospital; Weinstein(25) describes successful day-care programs, and Carmichael(26), Fox, Rutter and Smith(27), Freeman(28), Bierer(29), Kramer(30), Gussen(31) and Steinman and Hunt(32) discuss the value of day hospitals. Drubin(33), Oliver(34), Holman(35) and Cleobury(36) voice words of caution about newer trends in psychiatric rehabilitation. Drubin(33) fears that such community-oriented facilities will care for only certain types of patients and that the more chronic and long-term cases will be placed at a disadvantage, while Oliver(34) assumes that community services are a device to save

money. However, Carmichael(26) says the day hospital has demonstrated that the rehabilitation potential of chronic schizophrenics has been greatly underestimated, and Freeman(37) emphasizes that community services are not inexpensive. Basham(42) reports that chronic, long-term patients profit from movement toward the community. Similarly, Rafferty(38) says that a day treatment structure is beneficial to adolescents.

These newer trends in psychiatric rehabilitation indicate that the function of the mental hospital is changing. Tallman(39) believes "that the state hospital is becoming and will increasingly become a place where hospital psychiatry of a professionally high standard will be practiced" and that the impetus for progress is coming from state hospitals. O'Neill(40) feels that treatment methods must be developed within the hospital and integrated with the community. He is concerned over the tendency in America to develop community mental health services separate from the hospitals. It is interesting to note parenthetically that the precursor of the modern mental hospital was in existence briefly in Sicily almost two hundred years ago(Mora, 41).

Work, as a factor in rehabilitation, has received particular attention recently. Jones(44) writes of the importance of choosing work tasks that meet the needs of the individual patient. He believes that not just work itself but the patient's ability to interact with other people and to accept authority are of importance in the rehabilitative process. Schossberger(45) gives an account of a successful work village for mentally ill persons in Israel. A Berkeley, California toy manufacturer has set up an assembly line with 20 employees, all with histories of past mental illness(47). Probably this is the first time a concern has employed a staff with an almost 100% record of past mental disorders. Hubbs(48), Denber(49) and Freudenberg(50) describe successful sheltered workshops. These authors stress that the element of economic gain is a significant factor in the rehabilitation of psychiatric patients. Wheat, Slaughter and Frank(51), in discussing vocational rehabilitation, emphasize that opportunities must be geared to the changing needs of the patient.

The importance of recreation in rehabilitation is emphasized in 4 papers on the subject by psychiatrists(52). Other accessory methods are reported to be important adjuncts in rehabilitation. Music(53), hobbies(54), ex-patients as volunteers(55, 56, 57), ex-patients' clubs(58), college students(59), the family doctor(60), the public health nurse(61) and self-help organizations(62) all can play a significant part in restoration.

Many programs for the ever-increasing number of geriatric patients(63) are being developed(64, 65, 66, 67, 68, 69, 70, 71), all of which center around finding new objectives and giving new meaning to the existence of the elderly. Similarly, special programs are being developed to expedite the recovery of adolescents and children(72, 73, 74, 75).

Close follow-up and counseling are assuming an increasingly important place in rehabilitation. Patterson(77) says that the relationship between the counselor and the patient is the most important factor in successful rehabilitation, while Hamilton(78) emphasizes the community role of the counselor. Bettag(79) expresses the hope that by 1965 there will be departments of rehabilitation in all state mental hospitals and schools.

As in previous years, the periodicals contain many publications dealing with the relief of emotional factors that obstruct rehabilitation of the physically ill. Visotsky(80) states that the patient must adjust to a new image of himself, and Whitehouse(81), Becker(82), Fishman(83) and Willard(84) stress the importance of psychological factors in physical disability. It is gratifying to know that the U. S. Civil Service Commission now considers epileptics employable under certain conditions(85).

Whitten(86) feels strongly that "rehabilitation of the future will be more individual-need-centered and less agency-centered than before," while Efron, Marks and Hall(87) compare the effectiveness of individual-centered and group-centered activity and conclude that there is no essential difference in effectiveness.

All sorts of research projects in methods and facilities for rehabilitation are being undertaken, prominent among which are

experimental efforts to rehabilitate schizophrenics(88, 89, 90, 91).

Conferences on rehabilitation have been frequent during the past year(92-95).

Trevethan(96) reports on rehabilitation internationally and Maclay(98) reviews the major provisions of the New Mental Health Act in England and Wales. This legislation is the result of an extensive study and gives expression to an entirely new way in which mental disabilities can be dealt with. Other contributions from the foreign scene are: from England a new type of wing on a mental hospital(99), a factory that employs only mental patients(101), and an authoritative report on open hospitals(102); from Sweden, a plan for 5 open hospitals(103); and from Australia an account of the rapid progress of the open door policy(104). Kalinowsky(105) describes Soviet psychiatry and emphasizes how it is centered around dispensaries and is outstanding in its organization and therapeutic activity. Klumpner(106) gives an account of a psychiatric hospital for children in Moscow. The reader is urged to study Laughlin's survey of psychiatry in 6 European countries(107) in order to achieve a better understanding of the work of his colleagues in foreign lands.

Eight new books and booklets dealing with various aspects of rehabilitation have come to this reviewer's attention during the past year. Of these, the work of Greenblatt and Simon is outstanding(108). They report on rehabilitation during hospitalization and the post-hospital adjustment period as discussed at a conference of authorities in psychiatry, medicine, and the social sciences. Kurtz(109), in *The Social Work Year Book of 1960* considers problems of the aging, mental health and vocational rehabilitation. Gelber(113) reports on a study made to identify the needs of discharged mental patients in relation to public health nursing functions. *Troubled People on the Job*(114) offers excellent advice to supervising personnel in industry.

Several books and manuals on occupational therapy also have been published recently. This reviewer has seen ten. A manual that takes statements and quotations from textbooks on occupational therapy(116) orients the reader toward total re-

habilitation. Objectives, methods and media of occupational therapy for use with individual patients are discussed. Psychiatrists and occupational therapists dealing with prevocational and vocational problems should read *Tower*, a book(117) which deals with testing, orientation and work evaluation in rehabilitation. The World Federation of Occupational Therapists has published the proceedings of its second international congress(120), which includes discussion of the role and contributions of occupational therapy in rehabilitation of the mentally ill. A new and particularly well illustrated textbook of occupational therapy with an excellent bibliography(122) describes many techniques for the management of psychiatric patients. Another new book deals with occupational therapy in pediatrics and shows how it can be used beneficially in children with different types of emotional problems(123).

Publications in periodicals during the past year that consider occupational therapy and psychiatry have not been unusually numerous. Conte(126) visualizes the future effectiveness of occupational therapy as depending on the psychotherapeutic role of the therapist. Anderson and Gordon(127) tell why overspecialization in occupational therapy is undesirable. Reilly(128), Fry(129) and Huntting(130) discuss various research potentialities of occupational therapy. Llorens(131) says that psychological test results are a valuable aid in planning occupational therapy goals of emotionally disturbed children. Roberts(135), Dixey, Haslerud, Niswander and Rutledge(136) and Deane and Dodd(137) describe occupational and educational techniques that benefit the chronic mental patient, while Farrell(138) and Elson(140) emphasize the importance of the workshop as a part of occupational therapy. Specific activities as tools of occupational therapy are considered by other authors(Krygar, 141—clerical work, Etheridge, 142—patient publications, 143—creative writing).

CORRESPONDENCE

PSYCHIATRY AND ITS METHODS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : Dr. Walter D. Hofmann, in his letter in the August issue of this journal, touches on an issue deeply disturbing all thoughtful psychiatrists. In the last 40 years a unique situation has arisen almost unchecked. Psychiatry has allowed itself to be built up without checking extravagant therapeutic and scientific claims, as would be a matter of course in other specialties. The words of Ganet, "anarchy and dogmatism reigns in psychiatry," are even more true today than half a century ago.

Much psychiatric literature is repetitive and unproved while important areas are neglected.

So many psychiatrists naively assume that their observations are necessarily valid, encouraged by Freud's ambitious notion that the psychoanalyst becomes an objective instrument of science merely by removing his emotional bias by being analyzed. His was a revolutionary concept. Unfortunately however, it proved wrong. By now, most analysts agree, as did Freud at the conclusion of his life, that training analysis fails to achieve its objectives; indeed, Glover thinks the longer the analysis, the greater the element of suggestion. But the conclusion that the analyst is not entitled to

scientific license merely by virtue of having been analyzed, has not yet been drawn.

At the other end of the scale are the "research" publications. As Dr. Hofmann rightly points out, merely calling something "research" does not make it so.

Perplexed by the overwhelming manifoldness of the material, too many researchers pick over-simplified tangible trite data for control experiments. Bleuler said that psychiatrists tend to describe not what is most significant but what lends itself most easily to being described. This is still more true of the hypotheses of many researchers.

We cannot transfer the approaches of one science to another. Psychiatry must develop its own methods. Pseudo-exactness is no substitute for intelligent clinical observation. Psychiatry has been seriously handicapped by the tremendous professional pressure to conform. This has dampened originality and even deterred many medical doctors from entering psychiatry.

Melitta Schmideberg, M.D.,
Director of Clinical Services,
APTO, New York, N.Y.

Dr. Hofmann comments that Dr. Schmideberg's counsel and caution are "worthy of emphasis."

NEWS AND NOTES

CERTIFICATION IN CHILD PSYCHIATRY.—

The Committee on Child Psychiatry of the American Board of Psychiatry and Neurology, Inc. will conduct its next examination on February 6 and 7, 1961 in Chicago, Ill.

Applications for certification on record will be received up to September 21, 1961. All applications received after that date will be considered for eligibility for examination only.

All inquiries may be directed to: Dr. David A. Boyd, Jr., Executive Secretary-Treasurer, American Board of Psychiatry and Neurology, Inc., 102-110 Second Ave. S.W., Rochester, Minn.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The following candidates were certified as Diplomates in Child Psychiatry by this Board and its Committee on Certification in Child Psychiatry, March and October 1960.

MARCH, 1960

Finzer, William F., M.D., Pittsburgh, Pa.
Frank, Richard L., M.D., New York, N. Y.
Gilbert, Louis J., M.D., New York, N. Y.
Kaufman, Irving, M.D., Belmont, Mass.
Kaufman, S. Harvard, M.D., Seattle, Wash.
Lewis, Murray D., M.D., Rochester, N. Y.
Rabinovitch, Ruth, M.D., New York, N. Y.
Rapoport, Jack, M.D., New York, N. Y.
Rochlin, Gregory, M.D., Cambridge, Mass.
Sheimo, Stanton L., M.D., San Mateo, Calif.

OCTOBER, 1960

Adamson, William C., M.D., Rydal, Pa.
Altman, Sidney Irving, M.D., Philadelphia, Pa.
Belmont, Herman S., M.D., Elkins Park, Pa.
Bourg, Donald J., M.D., Denver, Colo.
Bucknam, Frank Gilbert, M.D., Hartford, Conn.
Burks, Henry L., M.D., Ann Arbor, Mich.
Call, Justin D., M.D., Los Angeles, Calif.
Caplan, Hyman, M.D., Montreal, Que.
Clements, C. Glenn, M.D., Cincinnati, Ohio.
Coda, Evis John, M.D., New Orleans, La.
DeMyer, Marian K., M.D., Indianapolis, Ind.
Gluckman, Robert M., M.D., Evanston, Ill.
Hayes, Marjorie, M.D., San Francisco, Calif.
Johnson, James A., M.D., Milwaukee, Wis.
Kohrman, Robert, M.D., Chicago, Ill.
Kraft, Irvin A., M.D., Houston, Tex.
Langdell, John Irving, M.D., San Francisco, Calif.

Littner, Ner, M.D., Chicago, Ill.

Lockett, Harold James, M.D., Northville, Mich.
Marten, George Wenceslas, M.D., Memphis, Tenn.

Mora, George, M.D., Providence, R. I.
Newman, Samuel J., M.D., Cincinnati, Ohio.
O'Connor, Robert Emmett, M.D., Madison, Wis.

Philips, Irving, M.D., San Francisco, Calif.
Plotsky, Harold, M.D., Washington, D. C.
Ragins, Naomi, M.D., Pittsburgh, Pa.

Zuger, Bernard, M.D., New York, N. Y.

AMERICAN GROUP PSYCHOTHERAPY ASSOCIATION.—The Fifth Annual Institute of the Association will be at the Henry Hudson Hotel, New York City, January 25-26, 1961.

The theme is the Application of Group Psychotherapy in the Treatment of some Major Psychopathological Syndromes.

Registration fee is \$35.00 for members and \$50.00 for non-members (which includes luncheon January 25 and dinner January 26).

The 5th Annual Institute immediately precedes the 18th Annual Conference of the AGPA January 27 and 28, 1961, at the same hotel.

Advance registration is necessary. For full program write to: American Group Psychotherapy Association, Room 516, 1790 Broadway, New York 19, N. Y.

SEVENTH INTERNATIONAL CONGRESS OF NEUROLOGY.—This Congress will be held in Rome September 10-15, 1961, under the

auspices of the World Neurologic Federation and of the National Institute for Nervous Diseases and Blindness of Bethesda.

Information is available from the President of the Congress, Professor Mario Gozzano or from the Secretary General, Dr. Giovanni Alemà, Viale Università 30, Rome.

The fifth International Congress of Electroencephalography and Clinical Neurophysiology will be held in Rome September 7-13, 1961.

Information may be obtained from the President of the Congress, Professor Mario Gozzano, or from the Secretary General, Dr. Raffaello Vizioli, Viale Università 30, Rome.

THIRD WORLD CONGRESS OF PSYCHIATRY.

—At this World Congress to be held in Montreal June 4-10, 1961, it is expected that there will be a large attendance of psychiatrists from the 70 different countries with which the Organizing Committee has been in touch.

For the first time since the World Congress in Paris in 1950 there will be an opportunity to speak about the development of plans based on the broad advances that psychiatry has made in these last 10 years.

A social program is being arranged for the evenings, and there will be separate daily programs of entertainment for the ladies of the Congress and for children in 3 age groups (5-9, 9-12, and teenagers).

A travel agency, Thos. Cook and Son/Wagon-Lits, has been appointed, and inquiries about group travel should be made to the agency's offices.

Registration at a reduced rate is available until January 15, 1961. Thereafter the full registration fee will be charged.

Full information may be obtained by writing to: III World Congress of Psychiatry, Allan Memorial Institute, 1205 Pine Avenue West, Montreal 2, Canada.

PSYCHOANALYSIS.—"Kairos" and the Therapeutic Process will be the subject of a paper by Dr. Harold Kelman, Dean of the American Institute for Psychoanalysis, to be given on the evening of January 25, 1961, 8:30 p.m. at the New York Academy of Medicine, 2 East 103rd St., New York City.

("Kairos" refers to a crisis or turning

point. Dr. Kelman will define some of the techniques by which the happenings in this phase of the therapy can be utilized toward effecting a favourable outcome.)

THE MARY PUTNAM JACOBI FELLOWSHIP.

—The Women's Medical Association of the City of New York offers the Mary Putnam Jacobi Fellowship to a graduate woman physician, either American or foreign. The Fellowship of \$1,000 will begin October 1, 1961 for a period of one year. At the discretion of the Committee, an award of \$2,000 may be given biannually. The recipient of the Fellowship will be expected to make a report at the end of the 4th month following which the balance will be awarded, subject to the approval of the Committee. The Fellowship is given for medical research, clinical investigation or postgraduate study in a special field of medicine. The recipient is expected to devote full time to the Fellowship, but exception may be made under special circumstances.

Applications may be obtained from Ada Chree Reid, M.D., Chairman, 118 Riverside Drive, New York 24, N. Y., and must be returned before March 1, 1961. Successful candidates will be notified not later than May 1, 1961.

BIBLIOGRAPHY ON SEX OFFENDERS.—The Division of Legal Medicine, Department of Mental Health, Commonwealth of Massachusetts, is compiling a bibliography on sex offenders and sex offenses. We would appreciate your forwarding to us any material consisting of articles or unpublished papers in this area. Please address your contribution to Norman A. Neiberg, Ph.D., Director of Psychological Research, Division of Legal Medicine, 33 Broad Street, Boston, Massachusetts.

GRADUATE COURSE IN CRIMINOLOGY, UNIVERSITY OF CAMBRIDGE.—The University of Cambridge has established a Post-Graduate Course in Criminology, to be given by the Institute of Criminology, and leading to a diploma, beginning in 1961. Each year the course will extend from October to July.

The programme will include 105 lectures and 90 seminars, dealing with all the major

aspects of criminology, criminal law and procedure. Individual work will be required at the seminars.

Instruction will be given by Dr. Radzino-wicz, the Wolfson Professor of Criminology, and staff, and by visiting lecturers, and experts from the Home Office.

Application forms for admission to the course are available from the Secretary, Institute of Criminology, 4 Scroope Terrace, Cambridge, England, and must reach the Secretary not later than March 15, 1961, for the course commencing in October.

TRAINING FELLOWSHIP IN NEUROANATOMY AND NEUROPHYSIOLOGY.—New York University Medical Center is offering a 3-months Training Fellowship with stipend of about \$1,000 in Neuroanatomy and Neurophysiology, beginning March 1, 1961. Candidates holding the M.D. or Ph.D. degree and interested in teaching or research in these subjects are eligible. Applications should be in by February 1, 1961. For information apply to: Dr. Louis Housman, Dept. of Anatomy, New York University Medical Center, 550 First Avenue, New York 16, N. Y.

CORRECTION

There were several typographical errors in our article "Contemporary Conversion Reactions: A Clinical Study," published in the April, 1960 issue of the *Journal*. The more serious error concerns the footnote on p. 906, the formula used to test the birth order and developmental role hypotheses. The formula with which we computed X^2 , with one degree of freedom was

$$\frac{\left[\sum \left(r_i - \frac{n_i}{i} \right) \left(\frac{i^2}{i-1} \right) \right]^2}{\sum \left(\frac{i^2}{i-1} \right) (n_i)}$$

The first term in the numerator was erroneously published as

$$\left(\frac{r_i - n_i}{i} \right)$$

This formula was derived from the one to the left of it, and there should have been an = sign between the two. Also, on the same page, column 2, line 18, $.05 < p < .01$ should obviously have been $.05 > p > .01$.

Frederick J. Ziegler, M.D.

WELFARE STATE

He who depends upon the state for protection, must pay for it by limitations on liberty. By every new demand which he makes upon his government, he increases its function and the burden of it on himself.

—WILLIAM GRAHAM SUMNER

BOOK REVIEWS

FROM THE DEATH-CAMP TO EXISTENTIALISM.

By Viktor E. Frankl. Translated by *Isle Lasch*. Preface by *Gordon W. Allport*. (Boston: Beacon Press, 1959, pp. 111. \$3.00.)

This book presents "A Psychiatrist's Path to a New Therapy." The author, Professor of Neurology and Psychiatry of Vienna University, was a prisoner in 4 Nazi concentration camps. This horrifying experience affected his psychotherapeutic orientation and led him to formulate "logotherapy," hailed by Allport as "The Third Viennese School of Psychotherapy." Using flashbacks, Dr. Frankl describes his 3 years in these camps and finally, in Part Two, formulates the basic principles of his theory. Originally published in German, this book is so remarkably transcribed and skilfully put together that one is barely aware of reading a translation.

The work has undeniable literary value and is also interesting from the psychological standpoint. Events evoked are so accurately caught they will be familiar to all ex-prisoners of Nazis. Descriptions of atrocities, indignities, and horrors prisoners constantly endured awaken deep sympathy and pity for the victims. These feelings tend to woo one to accept some of Dr. Frankl's theoretical conclusions.

In my opinion, our survival in camps was due to a combination of such factors as physical resistance, the degree of sharing in social relationships (lone wolves die early), and pure luck. Not always able to take an overall view of the situation, we tried hard to survive the way we knew best—the way we had learned, implicitly or explicitly, in the past. In retrospect, survival itself seems miraculous. No wonder survivors are tempted to believe their "recipes" have universal value—a mystic key to all of life!

Dr. Frankl's key is, in effect, Nietzsche's statement: "He who has a *why* to live can bear with almost any *how*." For him this is "a motto for all psychotherapy and education." From this sweeping generalization, he supplies his patients' lives with "meaning." I quote: "For, ultimately, man should not ask himself 'What is the meaning of my life?' but should, instead, realize that it is not up to him to question—it is he who is questioned by life; it is he who has to respond—to be responsible."

We know nothing about Dr. Frankl's pre-camp life or previous orientation. We know

what he went through and where he arrived. But, where did he start from? Is the journey an illusion? Did some metaphysical beliefs, implicitly held, become explicit?

I observed in camps that the sanity of some intellectuals was threatened not so much by cruelty and abuse as by the senselessness of their existence. They felt themselves above people living from day to day, who were supported by a simple, blind faith, and yet they themselves craved certainty; too "sophisticated" to harbour a candid faith, they sought certainty in teleology. I was amazed to hear in camps many educated people expounding irrational theories which even illiterates would not consider seriously. These were intellectuals who had relied on their elevated social position for security. As long as their status was recognized and respected, they felt that it was their "manifest destiny" to occupy their social position. Suddenly, in the camps, they were stripped not only of their social advantages but of the very prerogatives of human condition. The latter loss was easier to take since the misery was general. The loss of status, in contrast, threatened their self-esteem by hitting them individually. Once set apart, their natural attempts to salvage their "dignity," to retreat into reminiscence of the past were unwittingly permeated by their longing for the lost social supremacy. Little wonder that their strivings to escape the dreary reality were frequently misconstrued, mocked, and squelched by their fellow prisoners. Experienced as "uniqueness," isolation became bearable. Perhaps this answers Dr. Frankl's query why his quest for "dignity" was frequently resented by his camp-mates as a superior attitude. Hurt by their contemptuous and brutal reactions in addition to the general cruelty of the S.S. and Capos, he was unable to remain "unique" in the material world and took refuge in fantasy and metaphysics. There had to be a hidden, higher meaning to his misery and his very suffering made him unique.

For instance, he reports that, when suffering from extreme pain, he became disgusted with the situation and fancied himself giving a lecture on the psychology of the concentration camp to an attentive audience in a warm and well-lit lecture room. "By this method, I succeeded somehow in rising above the situation, above the sufferings of the moment, and I observed them as if they were already in the past." It seems obvious that Dr. Frankl, prevented from normal social interaction, obtained

it in fantasy. Lecture has no meaning outside of social terms. It was never really the abstract meaning of life that helped him out. It was always a concrete social experience.

Dr. Frankl wants us to believe that the world is one huge concentration camp and impotence is our prevailing condition. He preaches fatalism under the guise of "NOETIC," neo-platonic philosophy.

He is discarding reason because it failed to provide him with certainty. He seems to be unaware of the revolution which the theories of Quanta, Relativity, and the Principles of Indetermination of Heisenberg produced in our understanding of the role of scientific reason. It is the most powerful tool of investigation available to man but it is not meant to provide certainty. On the contrary, results have meaning only in operational terms and are always only provisional.

The quest for certainty does not properly belong to the scientific domain. Certainty may alleviate the individual's anxiety and therefore help him mobilize his energy against adversity. But it is intelligent action only which solves problems.

Rational and objective examination of the horrors of the concentration camps can be only undertaken in a social and historical perspective. The findings cannot fail to make us more aware of our social responsibilities. Nietzsche, of whom Dr. Frankl is so fond, believed that man's destiny is determined by his own acts. Another existentialist, Sartre, states that it is up to us to give a social meaning to our lives. One wonders if Dr. Frankl is aware that life has social meaning other than status consciousness?

The inconsistencies of his philosophy do not depreciate his often admirable behaviour in camps nor do they belittle his psychotherapeutic ability. But the fact that he can help his patients does not necessarily prove the superiority of "logotherapy." I think he helps them by making their life more related to society at large. The concomitant belief in absolute meaning and uniqueness of their lives does not improve the result. On the contrary, by making them less socially active, he also makes them potentially more vulnerable.

Regina Mental Health Clinic,
Regina, Sask.

PSYCHOSOCIAL PROBLEMS OF COLLEGE MEN.

Edited by Bryant M. Wedge. (Yale University Press, 1958. \$6.50.)

This collection of articles based on research and clinical experience by members of the

Division of Student Mental Hygiene of the Department of University Health at Yale University argues persuasively for considering "The College Age" a critical period for personality development. The multitude of influences brought to bear upon the individual at this age is reflected in the range of viewpoints represented in the chapter headings: The Psychosocial Position of the College Man; Satisfaction and the College Experience; Personality and Academic Achievement: A Questionnaire Approach; Clinical Study of Academic Underachievers; Leaving College because of Emotional Problems; An Investigation of Personality Differences Associated with Competitive Ability; Further Observations on Competitive Ability in Athletics; Who Uses a College Mental Hygiene Clinic; Group Psychotherapy with College Students; The Borderline Patient in the College Setting; Fear of Homosexuality in College Students; Identity Diffusion and the Synthetic Function; The Relationship of Intellectual Achievement to the Processes of Identification; and Treatment of Idiosyncratic Adaptation in College Students.

BERNARD LUBIN, PH.D.,
Indianapolis, Ind.

A POLYCHROME ATLAS OF THE BRAIN STEM.

By Wendell J. S. Krieg. (Evantson, Ill.: Brain Books, 1960. \$3.00.)

This small atlas of sectional drawings of the brain stem by the author consists of a set of illustrations of Weigert sections, in which each fiber is rendered in a code color, matched in opposite page to sections stained to demonstrate the neural cell bodies printed in blue to simulate the appearance of Nissl stain. This simultaneous presentation of the illustrations would enable the student to grasp and visualize the complex anatomical details of this important part of the brain. The text is brief and the quality of the illustrations confirm the artistry of the author.

J. BEBIN, M.D.,
Henry Ford Hospital, Detroit.

NATURAL SELECTION IN HUMAN POPULATIONS.

Edited by D. F. Roberts and G. A. Harrison. Symposia of the Society for the Study of Human Biology, vol. 2. (New York: Pergamon Press, 1960, pp. 76. \$3.00.)

A most stimulating symposium of the action of natural selection, mainly genetic, on human populations. Professor L. S. Penrose writes on "Natural Selection in Man: Some Basic Problems," Dr. A. R. G. Owen gives a most interesting account of new "Mathematical Models

for Selection," Dr. C. A. Clarke writes on "The Relative Fitness of Human Mutant Genes," Dr. P. M. Sheppard on "Natural Selection and Some Polymorphic Characters in Man," Professor Th. Dobzhansky on "Selection of Gene Systems in Natural Populations," and Dr. E. H. Ashton on the "Rate of Change in Primate Evolution."

The variability of man in all his varieties, once a fertile field for conjecture, is a problem which is now yielding to the investigative and analytic skills of a host of gifted workers. The present volume represents a short and highly readable account of the work that has been and is being done in this important field.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

THE HOMOSEXUAL IN AMERICA. By *Donald W. Cory.* (New York: Castle Books, 1960, pp. 334. \$6.00.)

After living a quarter of a century as a homosexual, the author presents his reflections on the homosexual in America. The topics discussed are sociology, psychology, patterns of behaviour, culture, types of adjustment and outlook in their relation to homosexuality. Appendices contain extracts from statutes dealing with homosexual offenses, and an extensive non-medical bibliography.

The author advertises his book as "Subjective Approach." It is really autobiographical and a plea for greater tolerance of the homosexual. It contains little that is not known to psychiatrists. Its purpose is disclosed in "this book was addressed to all the gay people in America."

GEORGE W. HENRY, M.D.,
Greenwich, Conn.

ETIOLOGY OF SCHIZOPHRENIA. By *G. U. Malis.* (Government Publications of Medical Literature (Medgiz), Moscow, 1959, pp. 224, price 8.40 rubles (Russian).)

In the past generation we have seen so many dragons slain by the St. George's bearing the emblem of Aesculapius that we are led to believe that all our medical ills will yield to the

sharpened spears of the scientist. We have seen consumption proven to result from the bacillus of Koch, malaria to be caused not by the miasma of the swamp but by the organism of Laveran, what was formerly a sort of mania (dementia paralytica) to result from the spirochete of Schaudinn. Since the birth of microbiology, there have been repeated attempts to marshal evidence that schizophrenia is due to a toxin, infection, or metabolic dysfunction. Among such endeavors have been Papez with his intracellular vibrios, more recently Heath and Company with their taraxein. Yet schizophrenia remains the Erlkönig of the psychiatric world, for it has never been accepted in spite of these myriad efforts that there is a specific toxin or a specific histology responsible for the mental symptoms.

Had we not suffered so many frustrations in the past in following the will-o'-the-wisp of schizophrenic etiology, this logical exposition of Professor Malis³ would convince us that at the basis of schizophrenia are toxic substances probably arising from a virus infection. The 7 chapters of this interesting book describe the characteristics of schizophrenic blood; the effect of this blood on the growth of tadpoles; the effect on the isolated heart of the frog; the toxic substances obtained from schizophrenic blood; the phytotoxic properties; the origin of these properties and their infectious nature; the virus factor in the pathogenesis of schizophrenia. The bibliography contains about 200 Russian references and upwards of 150 non-Russian. The experiments, most of which have been carried out by Malis in the past decade or so, are reported factually along with their controls, and although there is wide variation between the effects from different groups of schizophrenics, the difference between controls and patients is often very impressive. The language is in a clear Russian style.

If one finds himself transported by enthusiasm with these Russian experiments, he should as an antidote read the critical evaluation of Kety in *Science*, June 5 and 12, 1959.

W. HORSLEY GANTT, M.D.,
Baltimore, Md.

IN MEMORIAM

WILLIAM GORDON LENNOX

1884-1960

Dr. Lennox was born in Colorado Springs and always had a love of the west; in later years he spent many vacations in Texas where he was chairman of the board of the Elsinore Cattle Company of Fort Stockton. His early interest, however, was in medical missionary work and to this end he applied in 1909 (after graduation from Colorado College) to the Boston University School of Theology. He was denied admission because of his deficiency in Greek and Hebrew! He then turned to Harvard Medical School where he received the M.D. degree *cum laude* in 1913. While at Harvard he married Emma Buchtel (daughter of the Chancellor of Denver University and one-time governor of Colorado). Two daughters were born; one of them is now Mrs. H. B. Jansson of Maryland; the other is a doctor of medicine, Margaret Lennox-Buchthal of Denmark, who assisted in the writing of *Epilepsy and Related Disorders*.

After three years of hospital work, mostly at the Massachusetts General, Dr. Lennox went to Peking. The first year was spent in learning to speak Chinese and the next three years in the newly organized Rockefeller Medical School and hospital—four stimulating and satisfying years. In 1921 he wrote a thesis at the University of Denver on "A Study of the Health of Missionary Children" and received a Master of Arts degree. He then moved to Boston and began the fulltime task, in the Department of Neuropathology at Harvard, of trying to find out something about the origin and the treatment of epilepsy. This search continued for 33 years in association with various collaborators—at first with Stanley Cobb, H. G. Wolff and Hallowell Davis, but most productively with Dr. and Mrs. F. A. Gibbs. This trio worked as a unit for 11 years until 1945. Of the 241 medical publications that bear the name of Lennox, 28 were in collaboration with one or both of the Gibbs. Throughout 14 years there was continu-

ous support of the research by the Rockefeller Foundation.

Dr. Lennox was a member of many professional societies, and president of the Boston Society of Psychiatry and Neurology, of the Association for Research in Nervous and Mental Diseases, and for 14 years president of the International League Against Epilepsy.

Teaching appointments were in the medical departments in the Peking Union Medical School and Harvard Medical School, where he became Associate Professor of Neurology. Hospital assignments were successively at the Massachusetts General, Peter Bent Brigham, Boston City, Boston Psychopathic Hospital and lastly the Children's Medical Center as Chief of the Seizure Division.

No physician has more successfully dedicated himself to the study of one disease than has Dr. Lennox. It was characteristic of him to be thorough, courageous and persistent. First he did 5 years of spade work in the library and clinic bringing out (with S. Cobb) his first monograph "Epilepsy" in 1928. Then he moved on to more original and exciting fields. First he took up the study of cerebral circulation, and then in 1934 he saw the promise of electroencephalography and began work with Hallowell Davis. With the help of the new techniques of EEG the whole field of research in epilepsy moved ahead rapidly. Collaborating with Gibbs and many other colleagues, important contributions were made in therapy, genetics, etiology and social work. In 25 years the treatment of the epileptic patient and the understanding of his problems were miraculously improved.

Dr. Lennox was president of the Association for Research in Nervous and Mental Disease in 1946. Hundreds of letters came in congratulating him and sending financial aid to this work. At the December meeting

Wilder Penfield truly said : "This is a spontaneous, enthusiastic tribute from epileptics and from members of his own profession ; a tribute to a physician who is a scientist, a scholar, an historian and organizer ; a man,

above all, whose unfailing kindness has endeared him to his fellow man, to his colleagues and to the sufferers in his chosen field."

Stanley Cobb, M.D.

THE CURRENT STATUS OF ARMY PSYCHIATRY¹

COLONEL ALBERT J. GLASS, (M.C.), USA,
LT. COL. KENNETH L. ARTISS, (M.C.), USA,
MAJOR JAMES J. GIBBS, (M.C.), USA, AND
CAPTAIN VINCENT C. SWEENEY, (M.C.), USA²

INTRODUCTION

At periodic intervals since World War II, there have appeared authoritative reports on the current status of Army psychiatry. In 1948 and 1951, Caldwell(1, 2) reviewed the problems of Army psychiatry following World War II. Glass in 1953(3) and Peterson in 1955(4) described the operation and results of the Army combat psychiatric program during the Korean War. In 1956 Allerton and Peterson(5) surveyed 5 years of preventive psychiatry effort provided by Mental Hygiene Consultation Services which had been gradually reestablished with the onset of the Korean conflict. This presentation will report on another 4 years of the Army psychiatric program (1956-1960) and its further progress towards preventive orientation and practice.

It should be recognized that the conceptual framework and operational techniques as presently employed in the Army psychiatric program are a direct outgrowth of experiences with acute emotional disorders in World War II and the Korean conflict. Under conditions of wartime situational stress it became apparent that adjustment and military effectiveness were the complex resultant of multiple factors. The entire milieu of the soldier seemed to be involved which, in addition to the intensity of danger or deprivation, included motivation, cohesiveness, and other morale aspects of the group, the attitudes and strengths of buddies, the competency of leaders, the efficiency of communication, the adequacy of training, the degree of physical fatigue, the quantity and quality of supplies and weapons and even the medical criteria and disciplinary penalties for removal from the

stressful situation. Personality configuration as a behavioral determinant while significant was rarely decisive and in most cases of less importance than situational and social forces. Indeed the frequency of emotional disorders seemed to be more related to the characteristics of the group than the character traits of the individual. It was this awareness of non-effective military behavior, as a more common result of difficulties in the environment and interpersonal relationships of the soldier than manifestations of individual psychopathology which has been responsible for a gradual displacement of psychiatric personnel from their usual role and location in a hospital and clinic setting to the military community. This field approach has permitted a more realistic observation of the maladjustment process; brought psychiatric personnel into a working relationship with military supervisors; and has made possible the utilization of milieu as a major instrument in the development of techniques for prevention and treatment. As a result, the Army psychiatric program has been developed in the following three areas of endeavor.

1. Primary Prevention: Attempts to favorably influence the conditions under which soldiers may live, work or fight so that there is less likelihood of disabling maladjustment.

2. Secondary Prevention: The early recognition and prompt management of emotional or behavioral problems on an outpatient basis while the individual, still a member of his unit, struggles to cope with his environment or situation.

3. Tertiary Prevention: The employment of milieu as the principal therapeutic tool for persistent and severe mental disorders who require hospitalization. This technique, still exploratory and in the research stage, was designed to reduce chronic disability and produce a sufficient degree of rehabili-

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Office of the Surgeon General, Dept. of the Army, Washington 25, D. C.

tation so that favorable cases can be returned to effective military duty.

In recent years, including the period covered by this report, Army psychiatry has expanded those procedures and methods that may be profitably applied in the foregoing several areas of preventive psychiatry which have come to include disciplinary problems as well as symptom disorders. The objective of Army psychiatry has become the reduction of non-effective duty performance due to psychological reasons regardless of manifestations.

PRIMARY PREVENTION

In the area of primary prevention, the staff advisory function of the military psychiatrist is of paramount importance. Experiences indicate that the effectiveness of the psychiatrist in this role cannot be equated with the merit or excellence of his recommendations. More important is the quality of the relationship established by the psychiatrist with commanders and other supervisory personnel which to a large extent determines whether his suggestions will receive favorable consideration. Generally this relationship develops as a result of the activities of the psychiatrist in his professional management of referred problems. Unrealistic recommendations for special handling or assignment without reference to the practical limitations of the military situation or the forwarding of psychiatric reports replete with professional jargon produce a negative impression and the psychiatrist is judged accordingly. On the other hand, the psychiatrist who not only displays professional skill in the management of individual cases but renders decisions and recommendations which are meaningful and relevant from a military standpoint becomes highly regarded as a medical officer "with his feet on the ground." The psychiatrist, new to the service, cannot hope to achieve such military sophistication by limiting his professional activities to a traditional office or hospital practice. In order to acquire this background knowledge he must acquaint himself with the military environment, its rules, regulations, culture, mores and operational procedures by frequent visits to various post

or unit activities usually in connection with individual case referral.

When the psychiatrist establishes a favorable advisory relationship with military leaders a usable channel of communication is created for the transmission of psychiatric, psychological, and sociological information. This communication mechanism has been utilized as an instrument of primary prevention by psychiatric personnel as follows :

Firstly, there is the impact upon the involved non-commissioned and commissioned officer when the psychiatrist deals effectively with an individual case. These military supervisors are comparable to the so-called "caretakers" of civil life(6) occupying a role much like that of a foreman or teacher, or even a parent. Thus they are in an optimum position to exert a favorable influence upon the adjustment of subordinates. When military supervisors are afforded an opportunity to better understand the underlying causes of deviant or neurotic patterns of behavior, they often become more knowledgeable in the management of personnel as well as more efficient in the early recognition of maladjustment problems.

Secondly, there is the more direct employment of the military psychiatrist staff advisory function aimed at changes of rules, directives and regulations. Psychiatrists assigned to a major headquarters are concerned with personnel policies such as selection criteria for induction or enlistment, assignment limitations, medical and administrative standards for retention and discharge and procedures for the rehabilitation or elimination of individuals who exhibit deviant behavior. At the level of post headquarters and operational units, the psychiatrist submits recommendations which are relevant to local problems such as the early recognition and correction of disciplinary offenders, maladjustment of trainees, accident prevention and morale difficulties of particular units. An invaluable tool for the military psychiatrist at all levels and one which offers impressive evidence to commanders is the epidemiological approach. By this technique the psychiatrist can demonstrate significant differences in the incidence of non-effective behavior among units

of a post or division who are apparently exposed to the same environmental hazards and hardships. These data raise questions which inevitably focus attention of senior commanders upon the important areas of leadership or situational circumstances which could account for such differences among units.

SECONDARY PREVENTION

Secondary prevention, or the doctrine of early identification and prompt treatment received its major impetus during World War II when Army psychiatrists were confronted with a vast number of acute and apparently disabling emotional disorders. Hospitalization was repeatedly demonstrated to have little or no beneficial influence. For this reason psychiatrists, both in oversea theaters and in the United States, spontaneously moved to establish outpatient psychiatric units near troop concentrations. Out of these experiences were evolved the secondary prevention techniques of Army psychiatry as exemplified by the current practices of the Mental Hygiene Consultation Service which has become a permanent facility on most Army posts in the United States and an integral component of the medical service of all oversea divisions.

The Post Mental Hygiene Consultation Service is located near the troop population. It functions as an operational center from which personnel accomplish assigned tasks in the field. The staff consists of psychiatrists, officer social workers and clinical psychologists, enlisted social work and psychology assistants, and supporting clerical personnel. To insure continuity of patient care the senior psychiatrist of the Mental Hygiene Consultation Service is also in charge of the relatively small psychiatric inpatient service of the local Army hospital. Referrals are derived mainly from unit commanders and post dispensaries.

In recent years the operational practices of Mental Hygiene Consultation Services have undergone a gradual but definite change in the direction of a so-called field service approach(7). Particularly in basic training centers and other large posts there have been developed techniques of sending field workers, usually mature enlisted social work assistants, to interview the referred

soldier in his unit area. This intake procedure avoids the usual clinic atmosphere and its suggestion of illness or accentuation of dependency needs, prevents the excess loss of training or duty time and facilitates the gathering of collateral information from others, particularly military supervisors. It has also been found that the soldier in his own surroundings can discuss personal and situational problems more freely with another enlisted man than in the usual intake interview accomplished at the clinic building.

The enlisted social work assistant is given instruction in this peripheral or milieu approach, preparatory to his field assignment. Further training includes working with an experienced enlisted field social worker prior to assuming responsibility for handling referrals. The enlisted field worker endeavors to identify the salient features of the adjustment problem which includes the gathering of pertinent collateral information. Then he discusses the case with his supervisor, usually a social work officer, concerning the further exploration and management of the problem. One Mental Hygiene Consultation Service on a large basic training post utilizes group therapy as the preferred method of further treatment. Therapy groups have been established in each training regiment which are conducted by a social work officer with an enlisted field worker serving as a recorder. Other Mental Hygiene Consultation Services mainly employ individual counseling by a social work officer or an experienced enlisted field worker supervised by a professional officer of the clinic staff.

The social work staff's handling of routine referrals permits the psychiatrist to function as a consultant for the difficult, or controversial cases. In addition, the psychiatrist evaluates at the clinic those individuals who present suspected organic disease, psychotic or severe neurotic symptomatology, and problems of serious administrative consequence. The psychiatrist takes every opportunity to discuss individual case referrals with the appropriate unit commander by phone or preferably in person rather than rendering formal written reports.

The operational practices and thus the

effectiveness of the Mental Hygiene Consultation Services are influenced to a large extent by the psychiatrist's assertive leadership, confidence and experience with the field approach. As the leader of the clinic group the psychiatrist frequently meets informally with his staff to discuss policies and specific problems. He conducts case seminars and takes other occasions to educate and train his staff in the use of techniques appropriate to their development.

In order to prevent the recidivism of military offenders, stockade⁸ screening techniques initiated on several posts (8, 9), were later elaborated into an Army-wide program through the combined efforts of the Office of The Surgeon General and the Office of The Provost Marshal General. In this program Mental Hygiene Consultation Service personnel make regularly scheduled visits to the stockade. Each new prisoner is interviewed by an enlisted social work assistant who also gathers pertinent collateral information whenever possible. Equipped with this intake data and the observations of confinement personnel, the social work officer interviews each case and in consultation with the psychiatrist makes recommendations to the confinement officer concerning clemency or parole. The psychiatrist interviews all prisoners who are considered to present serious or unusual problems in behavior and all prisoners who are deemed unsuitable for further military service. In the latter case the psychiatrist renders an appropriate recommendation for administrative discharge. Prisoners restored to duty are given assistance by the field social work personnel with problems of unit reintegration. Mental Hygiene Consultation Service personnel meet periodically with the confinement staff to discuss techniques, attitudes, and other measures which may enhance the correctional atmosphere of the stockade.

Experience with the stockade screening program has shown that by the time the soldier was involved in sufficient difficulty to require confinement, often he had de-

veloped fixed, deviant patterns of behavior and was neither interested in, nor amenable to, corrective measures. It seemed reasonable then, to devise a method of aiding these individuals at an earlier stage of their maladjustment. Since few soldiers are confined as the result of their first court-martial, this event has been utilized as a means of recognizing the early identification of the problem soldier and require psychiatric evaluation and possible treatment at this time. This procedure is gradually being implemented on many posts in the United States with the endorsement and cooperation of the local post commander. In this first court-martial screening program, personnel of the Mental Hygiene Consultation Service function in a manner similar to the stockade screening effort as described above.

TERTIARY PREVENTION

Timely and aggressive intervention aimed at "heading off" the development of chronically disabling states has long been one of the major prerogatives of preventive medicine. Army psychiatry, well aware of the significance of such tertiary preventive measures, has added research projects, designed to come to grips with this problem, to its already broad program conducted at the Walter Reed Army Institute of Research under the direction of David McK. Rioch (10).

Early in 1956, one of the authors, Lt. Col. Kenneth L. Artiss, M.C., was assigned to Walter Reed Army Institute of Research to investigate the potential value of milieu therapy as an adjunctive measure to the already established treatment procedures then in use at Army psychiatric treatment centers. To thoroughly test the method it was decided to use acutely schizophrenic soldiers as subjects.

A ward at Walter Reed General Hospital was provided, beds removed until only 10 remained. It was staffed by one physician, one nurse, 12 to 14 neuropsychiatric technicians (corpsmen or attendants) for the 24 hour care of 8 to 10 acutely schizophrenic soldiers. A comprehensive feedback type of reporting system was established, using verbatim notes, tape recordings and

⁸ The Army stockade is a confinement facility for the incarceration of military personnel who have committed relatively minor offenses. In contrast, the Army disciplinary barracks normally provides for the confinement of the more serious military offender.

a high level of intra-staff communication as its main tools (11).

In the 3½ years of operation, this Milieu Therapy Unit, limiting itself to 6 months or less of treatment, has returned 64% of its treated patients back to military duty. While long-term follow-up information has not as yet been completed, initial surveys indicate that over-all results may turn out as encouraging as the percentage of patients returned to duty. Since these results were obtained with no specific attention paid to criteria of treatability and by a pilot-project staff, further exploratory work is being undertaken to determine the effects of selection of patients, selection and training of staff members, and staff intercommunication systems. Another pilot-type ward has been in operation at Valley Forge General Hospital for well over one year.

In order that information obtained from the patients during treatment could be evaluated in terms of relevancy to present change as well as past history, two separate investigative teams were used concurrently; one team conducted tape recorded interviews with fellow squad members and work associates of the hospitalized soldiers, and the other team visited the home, community, and school for definitive data. Through the use of this method it has been demonstrated (12) that the schizophrenic symptom may be used as an informative and communicative device; and that, furthermore, analysis of its social usage may contribute heavily towards understanding the "major message" by the use of which the patient deals with his society in a goal directed manner, having specific aims in view.

Group movements, group values and group processes contribute significantly to the discrete momentary behavior of the individual. Such a statement as this may now be successfully defended by reference to the accelerated accumulation of research findings in social psychology during the past 30 years (13); by the experiences of combat psychiatry (14); as well as by the findings of multi-disciplinary research in social psychiatry (15) during the past decade. Milieu therapy draws from all these sources in addition to some more definitely therapeutic endeavors of recent years, such as those of

Harry Stack Sullivan at Sheppard and Enoch Pratt Hospital (16), Maxwell Jones in England, and Harry A. Wilmer with Navy personnel.⁴

The basic philosophy used by the treatment unit appears to contain three major elements:

1. *The schizophrenic can be understood.* This is to say that if enough trained people work with him closely enough and correlate their observations, his "major message" will become clarified and his behavioral goals known.

2. *Understanding him helps him.* This is to say that "being understood" is a major step in the direction of successful group or social living—in that it leads to relatedness (17).

3. *Working with others is a therapeutic (learning) experience for him.* This is to say that his previous attitudes have prevented his smoothly learning social skills—operationally he is found to be socially infantile and to "recover" must accumulate role-taking abilities in groups, just as others do.

This treatment group which includes staff and patients, has a message for its single patient members which is as follows: "your problems are my problems, and my problems are your problems; we'll not abandon each other." At first glance this message may seem unrelated to combat psychiatry but upon closer inspection it serves to remind us of one of the significant lessons learned from wartime stress relative to the supportive impact of group cohesiveness.

RESULTS

The rates indicated in the statistical data to be discussed below express the incidence of phenomena as they occur in a thousand troops during a given calendar or fiscal year.

Chart 1 portrays a decreasing rate of psychiatric hospitalization⁵ during and since the Korean War coincident with a steady increase in outpatient psychiatric treatments. This chart, previously reported by Allerton and Peterson (5) on the basis of results up to and including the year 1955, illustrates an additional 4 years of experi-

⁴ For a more complete bibliography see Reference 12, pp. 38-39.

⁵ Includes individuals admitted to quarters and excused from duty for more than 24 hours.

HOSPITAL ADMISSION RATES AND OUTPATIENT VISITS' RATES PSYCHIATRIC CONDITIONS, PER 1000 TROOP STRENGTH PER YEAR FOR ACTIVE DUTY ARMY PERSONNEL WORLD WIDE

*PRIOR TO JULY 1956, DATA REPRESENT THE NUMBER OF TREATMENTS ADMINISTERED BY ARMY TREATMENT FACILITIES FOR NP CONDITIONS PER 1000 AVERAGE STRENGTH PER YEAR. BEGINNING WITH JULY 1956, DATA REPRESENT THE NUMBER OF VISITS TO ARMY MEDICAL TREATMENT FACILITIES FOR NP CONDITIONS. INCLUDES A CONSTANT, APPROXIMATELY 2% ADMIXTURE OF NEUROLOGICAL CONDITIONS.

**OUTPATIENT DATA FOR 1951 ARE FOR THE PERIOD JUNE-DECEMBER ONLY

ence with secondary prevention during a peacetime era. It should be noted that total psychiatric admissions declined to 7 per thousand per annum in 1959, the lowest rate of a 22-year period (1938-1959) for which comparable statistical data are available (18). However, admissions for psychotic disorders have been less affected. Apparently extramural management has not been so successful in preventing the hospitalization of the more severe mental disorders. Indeed, admission rates for psychoses in the U. S. Army have been relatively constant for over 40 years regardless of war or peace or other environmental variables. The decreased incidence of psychoses since 1955 as indicated in Chart 1 in actuality a gradual decline, is perhaps best explained by a reduction in the input of new military personnel: (See Table 1.) It is known that 65 to 75% of psychotic disorders in military personnel arise from men with less than two years of service.

A legitimate question may be raised con-

cerning subsequent effectiveness of those individuals who were maintained on a duty status. A partial answer to this question is given in Chart 2 which illustrates a gradual decrease of medical discharges for psychiatric illness since World War II. Except for a temporary rise during one year of the Korean War (1951) medical separations for psychiatric reasons continued to decline even during the wartime period and thereafter. These data indicate that the prevention of hospitalization did not produce mental disease so severe or chronic as to require medical separation. From other statistical data not shown here it can be categorically stated that there has been no compensatory increase of medical separations for illness or injury which could account for the discharge of psychiatric disorders concealed as organic or "psychosomatic" disease.

Any evaluation of a program aimed at the reduction of non-effective military performance must include its impact upon the incidence of behavioral abnormalities which

CHART 2

SEPARATIONS FOR DISABILITY DUE TO PSYCHIATRIC DISORDERS U.S. ARMY

(1938-1960)

(SEPARATION RATES PER 1,000 MEAN STRENGTH PER YEAR)

were sufficiently deviant as to cause removal from duty. It may be argued that decreased rates of hospitalization and medical discharge for psychiatric illness could be accounted for by an increase of administrative separations for unsuitability, unfitness, misconduct and the like. To shed light upon this question, Chart 3 gives rates of administrative separation for various causes from 1942 through 1959. It is apparent that elimination for behavioral reasons reached their lowest levels during the war years (1942-1945/1951-1953). This appears to be a regular recurring phenomenon which is believed due to more liberal policies of retention during wartime and a dilution effect from large inputs of inductees who generally require considerable time before their share of behavioral and disciplinary problems result in elimination procedures. In sharp contrast is the marked rise of administrative discharges in the postwar period. The smaller and cadre-type Army in peacetime has less opportunities for the utilization of marginal personnel particularly those who exhibit unsuitable or deviant be-

havior. There are also a number of behavioral and disciplinary problems from the previous wartime period which ultimately result in administrative and court-martial action in the postwar era. It should be noted that following the Korean War, rates of discharge for administrative and disciplinary reasons did not rise to nearly the high levels of the post-World War II period. It is herein contended that secondary prevention is at least in part responsible for this result. Mental Hygiene Consultation Services which were reestablished during the Korean War were continued and strengthened following the cessation of hostilities in contrast to their discontinuance with the rapid demobilization after World War II. Moreover, beginning in 1958, administrative discharges have begun to decline along with the decrease of psychiatric admissions and separations. Note also the recent trend for administrative separations to result in a higher proportion of discharges under honorable conditions. This indicates that behavioral problems are evaluated early in the course of their maladjustment

CHART 4

STOCKADE AND ARMY DISCIPLINARY BARRACKS
PRISONER CONFINEMENT RATE PER 1,000 ARMY STRENGTH

before accumulating an impressive record of antisocial behavior or disciplinary offenses.

Chart 4 shows a marked drop in the number of disciplinary barracks prisoners from 1956 through 1959. This decrease has permitted the closure of 4 of the 5 Army disciplinary barracks. The decline in stockade inmates, while substantial, is not as large as the reduction of disciplinary barracks prisoners. This disparity can be accounted for by the fact that major emphasis in the preventive psychiatry effort has been made at the stockade level which involved prisoners confined for relatively less serious offenses. Prevention of recidivism at this point has its greatest impact in diminishing the potential number of persons who may commit repeated or more serious offenses and become disciplinary barracks prisoners.

Chart 5 demonstrates that the decrease of the prisoner population is due to a diminished number of offenders rather than a rapid movement of prisoners through confinement. Note the marked drop in general courts-martial since 1956 from which disciplinary barracks prisoners originate. In con-

trast there is only a modest decrease of summary courts-martial which infrequently result in confinement and of special courts-martial which produce the majority of stockade prisoners.

It is recognized that rates of mental disorders, behavioral deviants and disciplinary offenders which are included in the statistical data that have been presented are influenced by many factors other than the efforts of psychiatric personnel. Of particular relevance in this respect are changes in policies and regulations which affect the selection, utilization, retention and discharge of military manpower and thus the composition of the Army. Two important alterations in recent years are pertinent since on an empirical basis both of these changes favored the induction and retention of personnel less susceptible to psychiatric disorders and behavioral difficulties. These changes are :

1. Recent increases in pay and other career incentives which, together with a decrease in the size of the Army since the Korean War, has resulted in an increased proportion of soldiers with several years of service over that of men with less than two

years of service. It is well known that maladjustment problems are more prevalent among new arrivals to the Army as compared with individuals in their second and third enlistment. Table 1 shows the decrease in turnover of enlisted personnel in the post-Korean War period. Since 1957 the proportion of personnel with less than two years of service has decreased only slightly which is insufficient to account for the substantial decrease of prisoners and psychiatric admissions in the past three years.

2. Upgrading of intelligence criteria for retention and induction which was initiated in late 1957 and early 1958, respectively.

Table 2 indicates that these changes have considerably reduced the proportion of male enlisted personnel with educational levels of 8 grades or less in favor of men who completed high school. This raising of intellectual standards can be regarded as an important factor in decreasing non-effectiveness since in the past the prisoner group contained 3 times the proportion of individuals with eighth grade or less education than the general troop population. Also it

is a reasonable assumption that individuals with lower intellectual capability have greater difficulty in adjustment than persons of average intelligence and thus more frequently become psychiatric problems or disciplinary offenders. However, it should be noted that before the upgrading of intelligence standards in 1958, a marked drop in prisoner strength had occurred. In fact, 2 of 5 disciplinary barracks were closed in 1957.

Despite the undeniable influence of the recent changes in the composition of the enlisted strength of the Army and other possible influential factors, it is believed that the Army psychiatric program has significantly contributed to a consistent decrease in non-effective personnel.

SUMMARY

The primary objective of the Army psychiatric program is the reduction of non-effective military performance due to psychological causes. In recent years this program has been expanded to include disciplinary offenders as well as the usual psy-

chiatric disease categories. To implement this program, psychiatric personnel have been displaced from the hospital or clinic setting to the military community. This field approach has made possible the utilization of milieu as a major instrument in the development of primary, secondary, and tertiary techniques of preventive psychiatry. Statistical data are submitted which indicate that the Army psychiatric program has made significant contributions towards achieving the lowest recorded psychiatric hospitalization and medical discharge rates, and a marked reduction of the Army prisoner population.

CURRENT TRENDS IN REGARD TO CRIMINAL RESPONSIBILITY¹

MANFRED S. GUTTMACHER, M.D.²

It is not fantastic to suggest that we are on the threshold of a socio-psychiatric development that may prove to be as profound in its effects as when Philippe Pinel took the chains off the patients in the *Bicêtre*. To what extent Pinel, Tuke, and Chiarugi were personally responsible in creating, in their respective countries, the drastic changes which took place in the treatment of the insane, and to what extent they were merely the apostles of the social revolutions which marked the close of the 18th century, is a complex question. In the course of history there have been few individuals and few social changes that were not the product of their age.

In discussing current trends in regard to criminal responsibility, I shall first center my attention on the epochal achievements of the Court of Appeals of the District of Columbia that has, under the leadership of Judge David Bazelon, embarked on a pioneering effort to deal realistically and radically with the relationship of mental disorder to criminal behavior. Many legal leaders have branded the Durham decision as revolutionary. The intensity of this reaction could not have resulted from the rule alone, for that had been in force in New Hampshire since 1870, but rather, from the broad implications contained in the Durham opinion, viewed as ominous portents of the future.

The Durham decision was, in truth, a product of the times in which we are living. Only the year before the decision, a Commission of the British Parliament, headed by Sir Ernest Gowers had reported,

a preferable amendment of the law would be to abrogate the (M'Naghten) Rules and to leave the jury to determine whether at the time of the act the accused was suffering from a disease of the mind (or mental deficiency) to such a degree that he ought not be held responsible.

Law is a ponderous organism. For more than a century voices of protest had been continually raised from many quarters against the old rules of criminal responsibility, beginning with Dr. John Haslam, Dr. Isaac Ray, Dr. Henry Maudsley, and Sir James Fitzjames Stephens. Then there were the legal opinions of Judges Lemuel Shaw of Massachusetts, Somerville of Alabama, and of that remarkable triumvirate of New Hampshire jurists, Doe, Perley, and Ladd.

At the beginning of this century a dramatic and profound impetus to the understanding of human behavior came through the genius of Freud. His investigations, and those of his followers, showed that even the behavior of apparently healthy minded men is infrequently under full conscious control of the intelligence and that the actions of those who are less healthy are only to a very limited degree the product of deliberate planning and conscious control. Psychiatric contemporaries like Zilboorg, Alexander, and Karl Menninger have been creating a new understanding of anti-social behavior. The very foundations of the hegemony of the freedom of the will have been shaken. Legal leaders like Mr. Justice Frankfurter and Judge John Biggs and professors Sheldon Glueck, Dession, and Weihofen have shown an acute perception of the newer psychology and its, as yet largely unfulfilled, influence on criminal law.

During a short period of less than 20 years before the hearings in the case of Monte Durham, almost half of the states had passed sexual psychopath laws. The philosophical rationale of such legislation is recognition of the fact that many offenders cannot be properly segregated into two discrete groups, the insane and the sane, that there are individuals who have characteristics of both groups and should be dealt with accordingly.

I do not wish to detract from the importance of the Durham decision, nor from the unique brilliance of the opinion itself, which Mr. Justice Douglas characterized as "imaginative." Nor do I wish to minimize

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² 819 Pk. Ave., Baltimore, Md.

the moral courage of the jurists who framed it, even though the stage was in a measure already set for them. The granting of the Isaac Ray Award to Judge David Bazelon by our Association, is eloquent testimony of the attitude of American psychiatry.

One must surely admit that the Durham decision has had a profound and immediate effect. The fact that at least 6 state legislatures, those of New York, Massachusetts, Maryland, Pennsylvania, California, and Vermont have recently had bills introduced to redefine legal insanity shows the ferment that has been produced. Even though these bills failed passage in all but Vermont their introduction gives evidence of a nucleus of liberal dissenting opinion in each of these states.

The Durham Rule has been considered and rejected by 3 different Federal Courts of Appeal, by 3 Federal District Courts, the courts of 14 states and the Military Court of Appeals. This does not mean that each of these courts has considered the rule on its merits. In most instances it was rejected largely on technical grounds. The other Federal Courts, lacking the autonomy of the District of Columbia Court, felt they had to follow the M'Naghten Rules because of the Supreme Court decision of 1893. Most of the appellate state courts have held that changes in the rules of responsibility, because of their fundamental importance and the length of time that they have existed in their present form, should properly be the subject of legislation rather than of judicial decision.

It is the view of Judge Bazelon that the Durham Rule itself is of less importance than the more than 50 subsequent decisions, handed down by the Court of Appeals of the District of Columbia, to implement it properly. Any psychiatrist who has reviewed these opinions must be struck by their practical wisdom and by the breadth of psychiatric understanding that is inherent in them.

I have had the good fortune of reading in manuscript an unpublished paper on the Durham Rule and the decisions which followed it, by Mr. Abe Krash, a prominent member of the District of Columbia Bar. I have taken the liberty of using some of this material. Mr. Krash asserts that there

are 3 fundamental principles implicit in the Durham decision :

1. That mental disorder may play a significant part in a substantial number of criminal cases.

2. That hospitalization with treatment may in a number of instances prove to be of greater benefit to society than imprisonment of the defendant.

3. That existing rules and procedures are obsolete and inadequate for segregating mentally disordered defendants and for dealing with the manifold problems that arise with the insanity plea.

Let us now examine some of the more important decisions that have emanated from this court in the past 5 years, as an outgrowth of the Durham decision.

The defendant's ability to stand trial was considered in the Lyles case. The Court states that,

A paranoiac or a pyromaniac may well understand the charges against him and be able to assist in his defense. "To assist in his defense," of course does not refer to legal questions involved but to such phases of a defense as a defendant usually assists in, such as accounts of facts, names of witnesses, etc.

In *Gunther v. U. S.*, the Court held that fitness to stand trial was not purely a medical decision and that a court was required to make its own findings, since this issue involves "a judgment based upon a knowledge of criminal trial proceedings." These are important declarations, which deal with a problem of growing importance. It is my impression that courts and prosecutors have tended more and more to rely on unfitness for trial as a device by which mentally diseased defendants can be dealt with humanely through hospitalization, without exposing them to the vagaries of jury decisions, under current court procedures and the prevailing rules of responsibility. Defendants are committed to a hospital until such time that they are sufficiently recovered to be tried. Frequently the case is statted after a considerable period of time and the patient is released on recovery without trial. This legal circumvention is, I believe, one instance of what Mr. Justice Frankfurter meant when, in speaking of the M'Naghten Rules he said, "they are discredited by those

who have to administer them . . . they are honoured in the breach not in the observance."

In the Wear case the Court held that a request to have a defendant examined psychiatrically must be granted unless the motion were made in bad faith and the supporting grounds were frivolous. The examining psychiatrists are authorized to make whatever tests are necessary, even to hospitalizing the patient. In the Winn case the Court decided that such an examination should not be confined narrowly to fitness to stand trial but should be complete where it appeared that insanity might be made an issue.

In keeping with the opinion of the Supreme Court in *Davis v. U. S.* in 1895, the District of Columbia Court of Appeals has emphasized the heavy burden of the prosecution to prove sanity once it has become an issue through the introduction of data indicating mental abnormality. But, the Court stated that some evidence of insanity is needed, mere claim of loss of memory of the crime is not enough; however, it admitted that "some evidence" cannot be definitely defined.

In both the Stewart and the Wright cases, the Court stated that a psychiatrist is not forbidden from testifying as to the existence of an irresistible impulse or the capacity to distinguish between right and wrong, but that where such testimony exists the jury should be instructed that it is only relevant in determining whether the unlawful act was a product of mental disease or defect and is not controlling as to responsibility.

The Court has held that whether a sociopath is mentally diseased is a question of fact to be decided by the jury and that instructing a jury that a psychopath is not insane within the meaning of the law is a reversible error. I am informed that in practice most psychopaths are held to be responsible by District of Columbia juries, despite the fact that the staff policy of St. Elizabeths Hospital was altered in 1957 to include psychopathy among the mental diseases.

As a result of a 3-year study of the English laws governing insanity by a Royal Commission, a new set of acts has recently been passed by Parliament. Due, in no small

part, to the urgent advocacy by this year's Isaac Ray award winner, Dr. Maxwell Jones, who directed for more than a decade the Belmont Hospital, an institution primarily for character disorders, psychopathy is considered a certifiable mental disease under the new Act. This is decried by the more conservative leaders in psychiatry as well as in law.

The social malignancy of his behavior, his disruptive influence in the hospital, and the difficulty that he presents in treatment, makes the psychopath generally a most unwelcome patient. Many psychiatrists feel that the already overburdened therapists should not have to take time away from more promising treatment prospects. In response to a recent paper, in which I welcomed the admission of cases of this type to intensive study and treatment units, one of this country's leading jurists wrote me that he considered it doubtful wisdom to expend large sums of public money on these individuals, when there were thousands of promising youths who could not go to college due to a lack of funds. As important as is the education of our youth, it seems to me that there could be no greater boon for the future of our society than a real break through in the treatment of psychopathy. The belief that the psychopath is evil and therefore is not deserving of our best treatment efforts is prevalent among us. This is reminiscent of the attitude that at one time was reputed to the gynecologist, Dr. Howard Kelly, one of the founders of the Johns Hopkins Medical School and a deeply religious man. He is said to have believed that those who acquired venereal disease illicitly did not deserve the same consideration in their treatment as those who had acquired the infection innocently.

The dire predictions by many Durham critics that the decision would turn our mental hospitals into prisons because of the overwhelming number of defendants who would be found to be insane under it, have not eventuated. Of the 10,000 defendants charged in the District of Columbia Criminal Courts since 1954, 90 have been found not guilty because of insanity. Of these, 26 have been conditionally released and 4 unconditionally. Of this number only 3 have been involved in serious anti-social offenses,

probably a much better showing than would be found in a similar number released from the penitentiary after the completion of their sentences. According to the *Washington Post-Times Herald* that collected these data, the term of hospital confinement was not substantially different from their probable period of imprisonment, had they not been found insane. The experimental study of juries by the University of Chicago indicates that cases presented to juries with judicial instructions according to Durham do not result in an increased number of insanity verdicts.

One of the chief targets for criticism of the Durham Rule is the inclusion of the product element. It is largely on this basis that Professor Wechsler, the very astute Recorder of the American Law Institute's Model Penal Code, has opposed the Durham formulation. The District of Columbia Court of Appeals has spelled out its own definition of "product."

... we mean that the facts on the record are such that the trier of the facts is enabled to draw a reasonable inference that the accused would not have committed the act he did commit if he had not been diseased as he was. There must be a relationship between the disease and the act, and that relationship, whatever it may be in degree, must be, as we have already said, critical in its effect in respect to the act. By "critical" we mean decisive, determinative, causal; we mean to convey the idea inherent in the phrases, "but for," "effect of," "result of," "causative factor."

The relationships "are not intended to be precise as though they were in a chemical formula."

The Court has made some prudent observations in regard to psychiatric testimony. In *Carter v. U. S.* it declared,

Unexplained medical labels—schizophrenia, paranoia, psychosis, neurosis, psychopathy—are not enough. Description and explanation of the origin, development, and manifestations of the alleged disease are the chief functions of the expert witness. The chief value of an expert's testimony in this field, as in all other fields, rests upon the material from which his opinion is fashioned and the reasoning by which he progresses from his material to his conclusion; in the explanation of the disease and its dy-

namics, that is how it occurred, developed, and affected the mental and emotional processes of the defendant; it does not lie in his mere expression of conclusion. The ultimate inferences *vel non* of relationship, of cause and effect, are for triers of the facts.

This formulation of psychiatry's contribution to a criminal trial presents a challenge which, I fear, few psychiatrists are equipped to meet. Dr. Andrew Watson, in his excellent paper read at the 1959 meeting of the APA, concluded that this ideal was not then being attained by the psychiatric experts in their testimony in the District of Columbia cases. This directive by the Court, creates the forensic climate for which we have been clamoring. We must school ourselves to perform adequately in it.

It has long been my contention that the written case reports sent to the Court by our clinic in Baltimore should contain the full body of data available—definitive opinion and conclusions with excerpts are not enough. The court is, I believe, entitled to have the opportunity of appraising the thoroughness of our study and the reasonableness of its conclusions from the data which we had available to us.

In a very recent case, *Hopkins v. U. S.*, the Court reasserts that

while a lay witness's observations of abnormal acts by an accused may be of great value as evidence, a statement that the witness never observed an abnormal act is of value if, but only if, the witness had prolonged and intimate contact with the accused.

Those of us who are engaged in clinical psychiatry can readily attest to the wisdom of this dictum. The observational powers of most individuals are amazingly inadequate. How often we are told by the co-workers and companions of out and out psychotics, "he always seemed perfectly normal to me."

It has been held in the *Lyles* case that the written diagnosis of a psychiatric disorder is inadequate in the absence of the physician who made it. The psychiatric diagnosis is considered to be an opinion and not a record of "an act, transaction, occurrence or event." The Court has, I believe, wisely held in this opinion that psychiatric diagnoses are less certain and reliable at

present than are autopsy, toxicological, and many medical diagnoses.

In *Taylor v. U. S.*, the Court held that it was a reversible error if the instructions to the jury in the District of Columbia failed to inform them of the requirement of an indefinite period of psychiatric hospitalization on the finding of a verdict of not guilty because of insanity. Jurors should not be left with the misapprehension that the defendant will probably be institutionalized for only a short period and then released. This seems to me to be very important. One of the chief characteristics of a jury, and indeed one of its chief assets, is its practical nature and although the disposition of the offender is not supposed to be involved in the determination of its verdict, it has great influence unconsciously, if not consciously, in the type of verdict that is reached.

Mandatory commitment of defendants found not guilty because of insanity is the rule in only 9 states. In 12 states the court is empowered to commit the defendant if he is deemed dangerous to public peace and safety. In 8 states the court is given discretionary power to commit if the need exists, with no criteria nor means for establishing this need. A similar number of states provide that commitment to a hospital shall be made if the insanity is believed to persist at the time of trial. In 7 states present insanity becomes a separate jury issue to be resolved at the time of trial. In these states, if the defendant is found to have recovered by the time of trial, he is immediately and unconditionally released. This last plan seems to me especially unsound and tends to bring legal psychiatry into disrepute. One of the chief functions of the criminal law is to bring peace of mind to the citizenry. This necessitates further hospitalization and observation after an insanity verdict.

Stringent requirements for release from the psychiatric hospital, in cases in which there had been a "not guilty because of insanity" verdict, were spelled out in the *Leach* case. Improvement or remission of illness was not enough, there must be "freedom" from such abnormal mental condition as would make the individual dangerous to himself or the community in the reasonably foreseeable future." This decision in itself

did much to reduce the number of insanity pleas by sociopaths.

The Court has ruled in *Starr v. U. S.* that a patient cannot continue to be held merely because of a felonious character: his dangerousness must come from mental disease or defect.

This year the Court forthrightly set aside the judgment of guilty in the case of *Isaac v. U. S.* and directed that he be found not guilty because of insanity. Judge Prettyman, in the opinion in the *Isaac* case, outlines the procedural steps for the release of insane defendants: "First, the superintendent of the hospital certifies to 3 conclusions based upon his expert professional opinion; (a) *Isaac* is not suffering from a mental condition which (b) renders him dangerous to himself or to others in the reasonable future, and (c) he is entitled to an unconditional release; or the superintendent certifies that . . . he is entitled to be conditionally released under supervision." The court in which the person was tried, "in the exercise of a judicial judgment and in the absence of objections" of the prosecuting authority, "may accept the certificate of the superintendent and order the release of the person." But, the court may hold a hearing on its own initiative. If the prosecuting authority objects to the authority of the superintendent's certificate, a court hearing is mandatory. This opinion concludes with the statement, "The part of the court in the release procedure is not *pro forma* or merely technical; it is the performance of judicial acts, dependent solely upon the evidence and the judicial judgment of the court," of course, giving due weight to the opinion of the hospital superintendent.

To some it may seem paradoxical that this psychiatrically enlightened court has persistently refused to adopt the concept of partial responsibility. In 1946, a vigorous dissent was made by 3 justices of the Supreme Court in the *Fisher* case, in which they favored the concept of diminished responsibility. The Homicide Act, passed by Parliament in 1957, establishes the concept of diminished responsibility in England, patterning it after the Scottish doctrine, which has been in force for nearly a century.

There are, of course, no such entities as

sanity and insanity. The gradations from mental health to mental disease form a continuum. It is difficult enough to establish the point at which significant disease may be said to exist. When the task is further complicated by seeking to establish the limit at which a sufficient degree of abnormality develops to impair responsibility but insufficient to negate it, one has indeed a knotty problem and one that can only result in the fine spun reasoning that has marked expertising under M'Naghten. Doubtless, the desire to escape this morass has been in part responsible for the disinclination of the District of Columbia Court to recognize partial responsibility. Moreover, the finding of a mitigating but nonexculpatory degree of mental abnormality would not provide the defendant the opportunity of psychiatric hospital treatment, so that little good would be accomplished by it.

If a recent trend in Maryland can be considered typical, and I believe that it may be, there is an increasing tendency to temper M'Naghten justice in homicide cases by arriving at a reduced grade of responsibility through a finding that the accused, because of mental disorder, lacked the elements necessary to establish first degree murder.

The controlling case in Maryland is that of *Faulcon v. State*, heard in 1956. The opinion of the Court of Appeals stated :

1. The essential difference between murder and manslaughter, therefore, is the presence, or absence, of malice. In the absence of justification, excuse, or some circumstance of mitigation, malice may be inferred. . . . 2. To justify a conviction of murder in the first degree, the jury, or the court sitting without a jury, must find the actual intent, the fully formed purpose to kill, with enough time for deliberation and premeditation to convince that the purpose is not the immediate offspring of rashness and impetuous temper, and that the mind has become fully conscious of its own design. For a homicide to be "wilful," there must be a specific purpose and design to kill ; "deliberate," a full and conscious knowledge of the purpose to kill ; and "premeditated," the design to kill must have preceded the killing by an appreciable length of time, i.e., time enough to deliberate. Deliberation and premeditation need not have been conceived or have existed for any particular length of time before the killing.

That this is a good law, I have no doubt. But that the psychiatric expert has any special skills by which to determine with accuracy these important elements : malice, wilfulness, deliberation and premeditation, I have very grave doubt. To be sure, the average juror lacks this discernment also. Legally these are questions of fact and since the law requires that they be answered, the jury must do the best that it can with them, but I believe that they should not be asked of the psychiatric expert. All that should be required of him is to describe in detail the mental condition of the defendant at the time of his examination and, as far as he is able, what he can infer was his psychiatric condition at the time of the crime. To have the expert answer inquiries about malice, wilfulness, deliberation, premeditation, etc., is seriously misleading, because the jury will naturally conclude that he has some very special competence in this area and will be unduly guided by his answers.

It is much like the questions in regard to knowledge of right and wrong and the nature and quality of the act, asked under M'Naghten. It seems to me that the claim that under *Durham* the psychiatrist takes command of the trial is entirely untrue. He is testifying as to facts in which he has special competence. He is in a position to state whether his conclusions as to the psychiatric condition of the accused at the time of the offense are essentially an hypothesis, an opinion or a conviction, so that even his degree of certainty can be evaluated. The jury can also appraise his thoroughness and his competence. Under the old rules of responsibility and the old procedural methods of presenting testimony, with the "all or none" type of answer which is commonly given in response to categorical inquiries about fictional psychological entities, which the law has created, and with which the expert has little familiarity and no special competence, there is given to the expert's pronouncements a specious air of wisdom and certainty which is misleading and elevates the psychiatric expert to a commanding status in the eyes of the juror that is not deserved.

I have always been a proponent of the use of court appointed neutral experts in trials. I have maintained that although our

adversary method of trial may be a desirable means for presenting ordinary factual data, it is not the optimum method for presenting opinion evidence on scientific subjects. But perhaps, until we follow the course set by the District of Columbia Court and change the focus and the range of testimony generally required of the psychiatric expert, the conventional adversary method should be retained, so that the opinions of one set of experts can be used to nullify the opinions of those of the opposing set, leaving the jury free to exercise its independent common sense.

The test of responsibility proposed by the American Law Institute in its Model Penal Code has gained acceptance in many legal quarters. It reads :

1. A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality of his conduct or to conform his conduct to the requirements of law. 2. The terms "mental disease or defect" do not include an abnormality manifested only by repeated criminal or otherwise anti-social conduct.

This test, in slightly amended form, has become the law of Vermont. It has received, or is receiving, serious consideration by legislative committees in California, New York, Illinois, Wisconsin, and Maryland. In the 85th Congress a bill was introduced to make it the law of the District of Columbia.

The 3 psychiatrists who are members of the Advisory Committee to the drafters of the American Law Institute's Model Penal Code have vigorously protested against this definition. Even though they see it as an improvement over M'Naghten, in that it is not framed in the old familiar but vague ethical terms of M'Naghten and it avoids its rigidity and gives recognition to that vital aspect of behavior, the capacity to control conduct, they do not find it acceptable.

In a recent protest, Drs. Lawrence Freedman, Overholser, and I stated that we believed that no formula for determining criminal irresponsibility by reason of mental disorder can be acceptable which demands a degree of precision of definition which exceeds present knowledge and a fragmentation of human function which denies its es-

sential unity. "In our opinions the definition's concept of 'capacity to control' suffers from 2 deficiencies : it attempts to compartmentalize human functions out of the context of the functioning human organism and it makes a technical demand on the psychiatrist which he cannot fulfill." We further objected "to the attempted definition of sociopathic or psychopathic personality and the legal elimination of a psychiatric diagnostic condition when it is 'manifested only by repeated criminal conduct or otherwise anti-social conduct,' " which according to the commentary in the draft of the Penal Code was the purpose of the second part of its definition. We failed to see "how the law can determine that a compulsive repetition of a form of behavior is non-pathological." We expressed great doubt as to the wisdom and necessity of attempting to legislate on matters of psychiatric terminology and concept.

In this protest to the Advisory Committee, its psychiatric members stated that they favored the Durham formulations since it permitted all of the relevant psychiatric data to be introduced and to be integrated by juries in their decisions as to fact. We admitted that the concept of "mental disease" would change with advancing research and knowledge, but we believed that the Durham Rule would permit psychiatrists to testify in the light of the then current knowledge. It was our contention that the word "product" offered no insurmountable barriers to logic, to science, nor to common sense.

Perhaps no one has given more prudent advice in regard to adjusting to the changes in the attitude of law toward mental disorder than the great Oxford legal scholar, Sir Paul Vinogradoff, when he wrote nearly a half century ago :

... It is immensely important that popular notion should be brought up to a level with broad results of scientific study. By imperceptible degrees scientific discoveries are making their way into popular consciousness, and it is the duty of those who are in closer touch with progressive thought—lawyers as well as scientists—to promote by all available means the spread of knowledge on these subjects.

People are often shy of approaching the psychological study of legal phenomena, especially

of crime, because they are afraid of undermining the practical premises of social security by investigating closely the psychological motives of criminals. This apprehension seems based on a pure misunderstanding: the principle of social self-preservation requires adaptation to altered scientific views rather than adherence to antiquated theories and the grappling of juries in every single case with the perplexing problem of responsibility.

If we look with complete candor into the future we must agree with what Lady Barbara Wootton, one of England's leading social scientists, said in a recent British Broadcast entitled, "Neither Child nor Lunatic." The socio-psychiatric evolution, or revolution if you will, through which we are living, points in the direction which she has indicated. Her broadcast concluded with these words:

Personally, I do not see how this state of affairs can continue indefinitely. Nor, indeed, do I see any reason why it should. The only solution, as I see it, is to give up trying to draw the line between the responsible and the irresponsible, and to recognize that once we have departed from the comparative security of the

M'Naghten formula there is no logical resting place short of abandoning the questions of responsibility altogether. In fact, that is just what has already happened under the Mental Health Act. In the case of the psychopath, the question whether he can, or cannot, help his outrageous behaviour is simply not asked: the only issue is his need for, or probable response, to treatment. So perhaps in the end we shall come to that in the courts also. In that case everything except treatment—guilt, responsibility, and all the rest of it—would become irrelevant. At least such a system would be both humane and effective, which is more than can be said for what we have now.

Perhaps this sounds like the millennium. But people had such dreams, long before psychiatry, as such, came into being. It was Epictetus, the Stoic, who said during the 1st century, that the wise man should regard even the greatest criminal as one who was unfortunate and confused and should not be angered with him.

To be sure, this ideal is still a long way off, and doubtless it is better so, until the behavioral scientists learn a great deal more about effectively treating and preventing crime.

COOPERATION FOR RESEARCH IN PSYCHIATRY AND LAW¹

LAWRENCE ZELIC FREEDMAN, M.D.,² AND HAROLD D. LASSWELL, Ph.D.³

The study of the selection and training of physicians has made rapid strides forward in recent years. The psychiatric profession in all its branches is a beneficiary of this redoubling of concern for the recruitment and formation of the profession. It cannot be said that research upon the legal profession is as far advanced (1). We shall forego the temptation to deal in detail with the sophistication of the lawyer in psychiatric conceptions and methods, and of the psychiatrist in legal concepts and techniques (2). Perhaps it is enough to reiterate the importance of the problems involved, and to select for emphasis 4 topics of high importance for the future of creative working relations between psychiatrists and lawyers. We focus upon 1. The problems of communication, 2. Of professional values, 3. Of the subjective stresses of collaboration, and 4. Of competency on the part of collaborators.

PROBLEMS OF COMMUNICATION

Not enough attention has been given to the study of one of the principal tools at the command of both professions, namely, language. More investigation is needed to bring out the subtle influence of categories upon perceptions of relevance. Modern instruments of communication (and information) research are available to cast into high relief the categories and problem solving processes appropriate to legislator, advocate, judge and jury; and the categories and problem solving processes appropriate

to the psychiatric physician. The community's official decision makers are authorized to decide in the name of the body politic what preferred forms of human relationships are to be protected by his decisions. This is the basic job of the decision makers who formulate constitutional charters which provide the framework of goal and method within which legislators, executives, administrators, and judges work. The language of the legal formula refers to the institutional arrangements that are to be protected by authority; in a word, to the public order (3). The decision makers are authorized to use the terms and prescriptions of the legal formula, as embellished by proper authorities, to guide their problem solving activities when confronted by a broad problem of legislation or a question involving the fate of one accused person.

The physician is not able to make his best contribution if he is bound by this language. The Durham decision in the District of Columbia has been a landmark in clarifying this point; and in making it evident that the appropriate language of the physician is that of his own profession, plus illuminating synonyms in ordinary speech. Communications are most usefully studied in situations in which we can identify who with what intentions and capabilities is saying what in what channel to which audience with what effects. It is entirely feasible to observe and record the professional situations in which lawyers and psychiatrists operate, and to bring out significant likenesses and differences. For instance, the psychiatrist interviews, among others, patients, relatives of patients, physicians and other staff members. The lawyer also interviews, among others, clients, opposing and cooperating counsel, and witnesses. The psychiatrist testifies as an expert in the decision-making processes of the community. The lawyer's advocacy role in official proceedings is to examine witnesses and argue the claims of the parties whom he represents. These reminders are sufficient to suggest that much can be done in providing a common body of objective material about

¹ This paper was written with the assistance of the Foundations Fund for Research in Psychiatry. From a report presented to the Section on Legal Aspects of Psychiatry at the 115th annual meeting of the American Psychiatric Association, May 1959, Philadelphia, Pa.

language-in-action; and to suggest the possibility of principles of effective communication (4, 5).

PROBLEMS OF PROFESSIONAL VALUES

It is apparent that professional education does not now clarify the professional standards of lawyers and psychiatrists where their activities overlap. For instance, privilege and confidentiality of communications and records, as well as evaluation of capacity and competence to perform certain legal acts, involves the psychiatrists in making legally pertinent judgments. Experience shows that psychiatrists and jurists often misunderstand the basic assumptions of the other in protecting the rights of individuals and of groups. The psychiatrist thinks primarily in terms of his responsibility for the health of the patient, and interprets his license from the community as a recognition of his competence to defend the medical rights of a patient. The lawyer is accustomed to emphasize the fundamental importance of providing procedural safeguards by means of which all rights can be given effective protection by the community. Accustomed to view himself as the benign, therapeutic protector of his patient, the psychiatrist often cannot understand the lawyer's concern with the "rights" of the patient while under his care. The psychiatrist sees impartial, court-appointed testimony concerning mental states, commitment to mental hospitals and psychiatrically ill people, and medically determined dates of discharge as essential medical prerogatives for the optimal psychiatric welfare of emotionally disturbed persons whether or not they have violated legal codes. He finds it difficult to comprehend the lawyer's assumption that adversary experts, court procedures for admission to hospitals, and legally imposed limits for treatment within them constitute essential protection of the rights of the patient. This illustration serves to point up the necessity for clearer conceptualization by each of the professional "body-image" and social posture. It has become apparent that recruitment, self-selection and acceptance for training by the prospective professional schools may favor certain motivations and personality types within each profession. If we are to remove

these misunderstandings that so often arise, we need joint research teams to investigate specific cases and to subject them to mutual discussion and evaluation. A clear delineation of their respective roles, values and semantics is probably best carried out by disinterested social scientists with the active cooperation, as subjects, of adequate samplings of lawyers and psychiatrists representative of differing schools of thought, status level, backgrounds and age groups. In the course of these studies workable arrangements may be suggested and explored that provide guidance for the psychiatric hospital, the private physician and the public officials involved in typical dilemmas.

SUBJECTIVE PROBLEMS IN COLLABORATION

Perhaps equal in importance to the considerations we have just made are the personal motives and social qualities of the lawyers and psychiatrists who work together on research tasks. At present little attention is given these matters in the course of professional preparation. It may be diplomatic and strategic to deny the irrational strivings, the rivalries, anxieties and conflicts which inhere to a project bringing together men of varying professional backgrounds, and personal values and characteristics. But it is not realistic or constructive. While it would be sanguine to assume that the mere delineation of anticipated pitfalls at a personal level will eliminate them, certainly it is essential that they be delineated and anticipated if precious time, manpower, and financial support be not dissipated. Worse still, the original energy may be supplanted by frustration and disillusionment, not as a result of difficulties inherent in the social challenge, but as an artifact springing from the human dislocations within the collaborative team.

Professionally the lawyer and the psychiatrist have much in common as shared experience which could facilitate the preliminary stages of research collaboration. For example, both professions have perforce learned to conduct their observations on human behavior under conditions permitting maximum spontaneity of response of their subjects. Neither is hampered by the illusion that the laboratory is the only place to study the activities of man. Against

this is the much reiterated therapeutic ambition of the psychiatrist leading him to identify with his single patient as against the threatening and oppressive community, and the social concern of the lawyer, leading him to think in terms of the maximum good to the maximum numbers while trying to do least harm to its individual members.

Lawyers and psychiatrists belong to prestigious professions, which offer them successful, status-occupying positions in the community. This maximizes their tendency to maintain identity and minimizes the likelihood of their yielding autonomy and sovereignty. When the opportunities for "success" within one's own profession, using one's own language, sharing one's values with fellows are great, only a very particular subgroup selects itself out for collaborative enterprises with sceptical and "alien" brother disciplines. The ambivalences inherent in this situation are sharpened by the scepticism encountered by these interdisciplinary pioneers on both sides—members of their own professional group and members of the collaborating group.

PROBLEMS IN COMPETENCY

Intellectual preparation for collaborative work doubtless calls for realistic modesty about competence. It would be over-optimistic to assume that it is practicable to bring together an effective group, each member of which has sufficient information to encompass and incorporate even the basic principles of the collaborating disciplines. Another requirement for such a research team, therefore, is that the members

are capable and willing to devote the time and manifest the humility necessary to educate one another. As a corollary to this, the participants must be willing to eschew the defensive maneuver of claiming for themselves and their own disciplines "expertness" in all fields which fall within their professional prerogatives. For, even within any given discipline, it is unlikely that a single man encompasses the knowledge available to his entire specialty. For example, psychiatrists while medically and biologically trained, are hardly in a position to speak for medicine and biology except vis-à-vis their non-medical collaborators. Similarly, lawyers specializing in one or another subcategory of this massive field ought not to feel forced to pretend to a range of expertness beyond it.

THE COMMUNICATION OF SUICIDAL INTENT PRIOR TO PSYCHIATRIC HOSPITALIZATION: A STUDY OF 87 PATIENTS^{1, 2}

W. BRADFORD DELONG, AND ELI ROBINS, M.D.³

During the course of our studies of attempted and successful suicide, it became evident that persons who attempt or commit suicide frequently communicate their intentions prior to the act (1, 2). The present study was undertaken to assess the content, frequency, duration, repetitiveness, and relation to clinical diagnosis of suicidal communications in patients who were ill enough to be admitted to a psychiatric hospital, but who were selected without regard to suicidal communications or acts. This study was limited to *communications* (verbal or behavioral, for example, a suicidal attempt) concerning suicide rather than to thoughts about suicide, for two reasons: (a) It was believed that more reliable and valid information could be obtained about actual communications than about thoughts. (b) It was desirable to have the present data comparable to the data from a previous study of completed suicide. Information in the completed suicide study was available only from surviving informants, who could give evidence of communications of intent, but not of uncommunicated suicidal thoughts. In this paper we will report on the suicidal communications of patients at the time of admission to a psychiatric hospital.

METHOD OF STUDY

Selection of Patients.—The primary object was the selection of an unbiased sample of admissions to a psychiatric hospital, within the limits imposed by hospital admission policy. Renard Hospital, where this study was done, is the psychiatric hospital for

Barnes Hospital and Washington University School of Medicine and is designed for short-term psychiatric care, admitting chiefly private patients or paying staff care patients. The present group of 87 patients included 71 private and 16 staff care patients. The mean duration of hospitalization was 23 days.

Limitations of time and personnel made it impossible to include every patient admitted during the two months' study. The selection criteria were: every patient admitted between 8 a.m. and 5 p.m., Monday through Friday, was to be included if accompanied by an informant and if his admission did not occur while interviews with a preceding patient and his informant were in progress.

During the study, 242 patients were admitted; 155 were excluded (143 by our selection criteria and 12 unintentionally), leaving 87 patients studied (Table 1), or 88% of the 99 patients who fit the selection criteria.

A comparison of the hospital records of patients included with those of patients excluded inadvertently or because they did not meet the selection criteria showed that the two groups did not differ significantly with regard to proportion of the sexes, age, history of a previous suicide attempt, proportion who received EST during their hospitalization, duration of hospitalization, or discharge diagnoses (Table 2). The sample of 87 patients represents, therefore, a relatively unbiased selection of the total admissions to Renard Hospital.

Sources of Information.—There were 5 sources for each patient: (a) The admission history taken by the admitting resident, in the presence of the investigator. (b) An interview with the informant, almost always a relative, who accompanied the patient. (c) An interview and mental status examination of the patient. (d) A questionnaire to each patient's psychiatrist concerning suicidal communications, and inquiring whether concern about suicide was a rea-

son for his admitting the patient.⁴ (e) A review of the hospital records after discharge.

⁴ The questionnaire included the following questions: (a) Had the patient communicated suicidal intentions to you? (b) Had the patient, to your knowledge, communicated suicidal intentions to anyone else? (c) Had the patient made a suicide attempt? (d) Was the possibility of suicide a major reason, a minor reason, or not a reason at all for your decision to admit the patient to the hospital?

A systematic interview with the informant, averaging over one hour, was done immediately upon admission of the patient, and preceded the interview with the patient. It covered identifying items; chief complaint; symptoms and natural history of the present illness; school, arrest, job and marital history; alcoholic and drug intake history; a history of personal life stresses; and inquiries as to whether the

* Includes 55 patients admitted on weekdays from 5 p.m. to 8 a.m., 23 unaccompanied patients, 19 simultaneous admissions, and the 12 patients unintentionally excluded, but does not include the 46 patients admitted on weekends. Since the 109 turned out to be so similar to the studied patients the addition of the inadvertently omitted 46 weekend admissions probably would not have changed the comparisons appreciably.

† These are diagnoses made by the patients' own physicians at the time of discharge.

patient had ever expressed any of the 16 types of suicidal communications (see Table 4). The interviewer systematically asked every question of every subject but changed wording and explored further as the occasion demanded.

The interview with the patient was identical in content with that of the relative, with the wording changed to fit the patient. In addition, direct observations concerning the mental status were made at the time of the interview, done within 24 hours of admission, and which averaged somewhat over one hour.

Suicidal Communications.—Subjects were asked about suicidal communication at any time in the patients' lives, not only in the recent past. Responses were scored as definite suicidal communications if the patient and/or the informant believed that the patient seriously meant the communication at the time he made it and that the communication was a reflection of a disturbed and unusual mental state. If either the patient or informant gave evidence of a definite communication, even if the other denied or minimized it, the communication was still scored as definite. Not included were the patient's prudent attempts to arrange his affairs (for example, making a will or buying a family burial plot) in the absence of morbid preoccupation with death.

Diagnostic Criteria.—The patients studied were divided into 3 major diagnostic groups: manic-depressive disease, chronic alcoholism, and a miscellaneous group (Table 3). The diagnostic criteria used for

diagnosing manic-depressive disease,⁵ schizophrenia, conversion reaction, anxiety reaction, acute and chronic brain syndromes, sociopathic personality, chronic alcoholism, obsessive-compulsive reaction, and mental deficiency were those reported in previous papers (1, 3). Each of these diagnoses was made on the basis of specific symptoms (somatic and psychological) and behavioral disturbances, excluding suicidal communications. The application of rigorous diagnostic criteria left a relatively large undiagnosed group of 14 patients, 16% of the total sample. When diagnoses made by the investigators using the criteria of the study were compared with the diagnoses on discharge, satisfactory agreement was found. For the 48 diagnosed manic-depressive, 44 had a discharge diagnosis included in our definition of this psychiatric entity: manic-depressive disease, psychotic depressive reaction, involutional depression, depressive reaction, or reactive depressive (7 cases of the latter). Of the 9 cases diagnosed alcoholism, 6 had the same discharge diagnosis. The other 3 cases had discharge diagnoses of psychotic depressive reaction or depressive reaction, although in each instance excessive alcoholic intake was noted in the chart. For patients for whom some other specific diagnosis was made, an agreement occurred in 18 of the

⁵ This term is used to include the diagnoses of manic-depressive disease, manic phase; manic-depressive disease, depressed phase; psychotic depressive reaction; and involutional psychotic reaction, depressive type. Reasons for including all 3 kinds of depressions under this one term have been discussed previously (3). Perhaps a more usual name for this group of terms is affective reactions.

* Includes 41 patients in the depressed phase and 7 patients in the manic phase. The high proportion of manic-depressive patients has also been found in studies reported from other short-term, private psychiatric hospitals (4, 5), where a minimum of one-quarter of the patients have had this diagnosis.

† Chronic brain syndrome—5; schizophrenia—4; conversion reaction—4; sociopathy, obsessive-compulsive reaction, mental deficiency—1 each; undiagnosed—14.

20 cases. In the remaining 10 patients, the investigators were not able to make a specific diagnosis, whereas the discharge diagnoses included schizophrenia, acute brain syndrome, chronic brain syndrome, conversion reaction, passive-aggressive personality, and 5 depressive reactions of various kinds.

Persons Who Had Committed Suicide.—Comparisons will be made between the 48 patients of the present study with manic-depressive disease and 60 patients with the same illness who had committed suicide. These 60 suicides were all of the manic-depressives found in a group of 134 consecutive completed suicides previously studied. Selection, diagnostic criteria, and suicidal communications for the 60 patients have been described previously(2, 3).

Statistical Methods.—The chi square test with appropriate small number corrections was used for statistical comparisons of enumerated data between groups(8). For measurement data, the standard error of the means and standard error of the differences between means were calculated and the significance of the differences tested by

means of the t-test(8). A significance level of 0.05 or better was accepted as being statistically significant.

RESULTS AND DISCUSSION

We shall first describe the characteristics of suicidal communications in the entire group, and then compare and contrast the various diagnostic groups. Next, the correspondence between information given by the informant and by the patient will be analyzed. In the final section a comparison will be made between the present manic-depressives and the previously studied group of completed suicides with the same illness.

THE ENTIRE SAMPLE

Kinds of Communication of Suicidal Ideas.—There were 16 different ways of communicating suicidal intent in the entire group (Table 4). Four categories of communication occurred in more than one-third of the patients. These categories (No. 1-4, Table 4, last column) included state-

* $P < 0.05$

† In this and subsequent tables, the column heads "Patients," "Informants," and "Either" signify suicidal communications according to information received from the patient or the informant or from either, respectively.

x E.g., "I won't be here—get your parents to help you raise the kids"; "I'm going to die; take care of the babies"; "You'd better get me into the hospital before anything happens"; "It feels like I don't have much longer to live"; "Some day you'll find me dead"; "I won't be here tomorrow"; "This is the last time I'll see you."

ments by the patient that he wanted to die, that he would be better off if he were dead, that his family would be better off if he were dead, and that he intended to commit suicide.

Sixty-eight percent of the patients had expressed suicidal ideas in one way or another and 53% had expressed such ideas in one of the 5 more common ways (Table 5).⁶ The communication of suicidal intent in patients admitted to a psychiatric hospital for short-term care is, therefore, high. Most of these statements show a preoccupation with suicide and death. For only 7% of the patients were the suicidal communications thought to be a taunt or threat. Apparently in patients ill enough to be ad-

mitted to a psychiatric hospital, suicidal communications are not considered a way of manipulating the environment for ulterior reasons, but as expressions of feelings of hopelessness and of depressed feelings.

Men and women did not differ significantly with regard to the prevalence of suicidal communications (Tables 4 and 5).

Frequency, Repetitiveness, and Duration of the Suicidal Communications.—Suicidal communications tended to be repetitive, varied, and of recent inception. Sixty-eight percent of the patients who communicated suicidal ideas had made such communications repeatedly. The mean number of the 5 common kinds of communications was 2.49. For 66% of those who had communicated suicidal ideas, no such communications had occurred prior to the year preceding admission, and for 44% not prior to the 3 months preceding admission.

RELATIONSHIP OF COMMUNICATION OF SUICIDAL IDEAS TO CLINICAL DIAGNOSIS

The number of patients, 9, in the chronic alcoholic group is too small for statistical treatment. The number within any one specific diagnostic group in the miscellaneous group is also too small for statistical treatment, but the total miscellaneous group affords a relatively homogenous group with regard to suicidal communications, which

will be compared with the manic-depressive group.

Kinds of Communications.—Suicidal communications were much more often reported for patients with manic-depressive disease than for those in the miscellaneous group (Table 5).⁷ Eighty-one percent of the manic-depressives made suicidal communications, as compared with only 43% of the miscellaneous group. When the comparison is limited to communications in categories 1 to 5 only, 65% of the manic-depressives, compared to only 27% of the miscellaneous group, made suicidal communications. Patients with manic-depressive disease who are ill enough to be hospitalized have a

very high prevalence of suicidal communications.

When comparisons are made for the particular ways of communicating suicidal intent, the manic-depressives show a significantly higher proportion in 4 communication categories—statements by the patient that he would be better off dead, that his family would be better off if he were dead, that he intends to commit suicide, and that he cannot take it any longer (Table 6, last column). Additionally, a higher proportion of the manic-depressives use 14 of the 16 categories of communication, while a higher proportion of the miscellaneous group occurs in only 2 categories.

The high frequency of suicidal communications in patients with manic-depressive disease raises the question as to whether the examiner did in fact use suicidal communications as a criterion for diagnosing manic-depressive disease, despite the decision that

⁷ Because of the few patients within any one diagnostic category, e.g., conversion reaction, schizophrenia, etc., in the miscellaneous group, it is not possible to conclude from this study that none of these diagnostic categories has a high prevalence of suicidal communications.

the diagnosis should be made on the basis of other criteria only. However, the independence of the diagnosis from considerations of suicidal communication can be demonstrated by the facts that: 1. Other classic symptoms of depression⁸ were uniformly present. Of the 41 patients in the depressed phase (Table 3), all except 2 had 8 or more of the 15 leading symptoms of depression. 2. The course of the illness showed the distinctive pattern of manic-depressive disease: episodic and late onset. In 51% of the patients diagnosed manic-depressive disease there was a history of a previous attack with an interval free of symptoms prior to the current episode. In 53% of cases the age of onset (date of the first attack) was over 40. In the miscellaneous group (excluding the 5 with chronic brain syndrome) (Table 3), in contrast, only 20% became ill after age 40 and only 8% had had a previous episode of illness with an apparently symptom-free interval following it. Nor did the previous episode described resemble an episode of manic-depressive disease.

⁸ Fifteen symptoms were chosen as particularly diagnostic of the depressed phase: anorexia, weight loss, diminished libido including impotence or frigidity, difficulty falling asleep, sleeping fitfully, early morning waking, complaint of getting no sleep, low mood, fear of losing mind, thoughts of never becoming well again, hopeless future outlook, complaint of poor concentration, complaint of poor memory, complaint of not thinking clearly, and complaint that speed of thinking was diminished. Other symptoms common in manic-depressive disease (6, 7), feelings of guilt and worthlessness, and delusions of poverty and sin, were used as supporting evidence.

Frequency, Repetitiveness, and Duration of the Suicidal Communications.—The manic-depressive patients who communicated their suicidal intentions showed a tendency to communicate in a greater number of different ways than did the miscellaneous group, 4.0 vs. 2.0. This tendency reached statistical significance for the patients' reports but not for the informants' reports. There were no significant differences between diagnostic groups with regard to repetitiveness of suicidal communications or with regard to duration of communication. As might have been expected, because of the episodic nature of manic-depressive disease, there was a tendency for the manic-depressives to have a shorter duration of suicidal communications. Of the patients who communicated, only 22% of the manic-depressives, compared with 57% of the miscellaneous group, had first communicated their suicidal intentions more than one year prior to admission.

Influence of Age and Sex.—Since the manic-depressive group, when compared with the miscellaneous group, was older and contained more men (Table 3), the question arose as to whether sex and age rather than diagnosis may have explained the greater proportion giving suicidal communications in the manic-depressive group. That sex or age was not the determining factor was shown by the findings that in the entire group and within each diagnostic group, no significant differences in communication occurred between the sexes or between young and old. There was a slight but insignificant tendency for men to com-

TABLE 7

** $P < 0.01$ when manic-depressives are compared with the miscellaneous group within each column.

municate suicidal ideas more than women, but this was balanced by a slight tendency for the younger patients to communicate more than the older ones.

Patients with Chronic Alcoholism.—Although there were too few patients in the alcoholic group for statistical treatment, the alcoholics appear to be more like the manic-depressives than the miscellaneous group, in that a high proportion communicate suicidal ideas (Table 5). To demonstrate this similarity satisfactorily, a larger number of alcoholics would have to be studied.

Questionnaire to Patients' Psychiatrists.—The results of this questionnaire are consistent with the results already reported (Table 7). Physicians reported a relatively high prevalence of communication of suicidal intent for the manic-depressives (and the alcoholics) and a complete absence in the miscellaneous group.⁹ The fact that higher figures were obtained for each diagnostic group, respectively, by the investigators than by the private physician (compare Tables 5 and 7) probably results from the

⁹ The diagnostic groups were those determined by the investigators. The questionnaires were answered by the attending psychiatrists independently of the investigators' diagnoses. The correlation is, therefore, all the more striking.

investigators' use of a systematic interview inquiring specifically into suicidal communications. Whether the more complete eliciting of suicidal ideas by questionnaire has practical clinical usefulness is yet to be determined. The attending psychiatrist was also asked whether the possibility of suicide had been a reason for deciding to admit the patient. The manic-depressive group when compared with the miscellaneous group was admitted significantly more frequently because of the possibility of suicide.

CORRESPONDENCE BETWEEN INFORMATION FROM PATIENTS AND FROM INFORMANTS

A survey of Tables 4 through 6 indicates that patients and informants differed little in the proportions reporting particular categories of suicidal communication or reporting patients as giving any suicidal communication, although a few more informants than patients gave positive responses.

When the answers of each patient were compared with those of his own informant, a high degree of agreement was again found (Table 8). The amount of agreement between patients and their informants did not differ significantly between diagnostic groups. Agreement was higher when the

TABLE 8
CORRESPONDENCE BETWEEN PATIENTS' AND INFORMANTS' RESPONSES
CONCERNING SUICIDAL COMMUNICATIONS

Categories of Communication	Manic-depressive disease		Miscellaneous group		Alcoholism		Total sample	
	No.*	%†	No.*	%†	No.*	%†	No.*	%†

1-5 At least one + in any of the 5 categories	46	85	8	75	29	79	83	82

* No. = Number of possible agreements or disagreements for any category or combination of categories when each patient's answer was compared with his own informant's. The numbers are not identical with those in Table 3, column 3, because in 2, 1, 1, and 4 instances, respectively, it was not possible to do a complete interview with the patient and his informant.

† Per cent agreement between the patient and his own informant. The agreement could be a positive one—both answered affirmatively—or a negative one—both answered negatively.

communication was by means of an actual suicide attempt than when it was purely verbal. In addition to analyzing total agreements between the patient and his informant, affirmative answers alone were analyzed by interviewing both the patient and the informant. In categories 1 to 5, 41 positive responses were given only by informants, compared with 27 positive responses given by patients only (Table 9). This is further evidence that informants gave more positive responses than did the patients themselves. This excess of positive responses, however, is strikingly limited to category 4, the specific statement of intent to commit suicide. There is a 107% gain in information with regard to category 4, compared with an average gain of only 31% for the remaining categories combined. Apparently patients either tend to forget having made statements of intent to commit suicide or are less willing to admit having made such statements than to admit other statements concerning death and suicide.

The method of study previously outlined indicated that informants were always interviewed before the patients, and since they were interviewed first and tended to give more positive responses than the patients, differences cannot reasonably be

attributed to examiner bias.¹⁰ If such bias existed, it should have been in the direction of increasing the prevalence of communications reported by the patients, based on the prior information obtained from the informant. Further evidence that examiner bias was not important is the agreement of our results with those of Cassidy, *et al.* (6) who showed that manic-depressive patients, when asked only one question about having had suicidal thoughts, gave a positive answer in 45% of cases. In the present study, no single question elicited more than a 40% positive answer from the manic-depressives (Table 6). It was concluded, therefore, that reports of suicidal communications by the patients in this study were probably not falsely high.

COMPARISON OF THE PRESENT GROUP OF MANIC-DEPRESSIVES WITH A PREVIOUSLY STUDIED GROUP OF COMPLETED SUICIDES WITH THE SAME ILLNESS

The purpose of this comparison is to ascertain whether the communication of

¹⁰ To exclude bias rigorously, it would have been necessary to vary randomly the order of interviewing the patient and the informant and not to permit the same investigator to interview both a patient and his corresponding informant.

TABLE 9
CORRESPONDENCE BETWEEN PATIENTS' AND INFORMANTS' POSITIVE RESPONSES

5. Suicide attempts	10	2	0	0%
1-5 Total	70	27	41	42%
1-5 At least one + in any of the 5 categories	31	7	8	21%

* The individual diagnostic groups each showed the same pattern of differences as did the total sample.

† Increase in positive answers resulting from interviewing informants was computed by dividing positive answers by informants only (C) by total patient positive answers (A+B) and multiplying by 100. If category 4 is excluded from the total, and the percentage calculated for the remaining categories, the percentage gain is

26

$\frac{26}{31} \times 100 = 84\%$

57+26

suicidal intent is helpful in assessing the risk of suicide in a patient with manic-depressive disease. An examination of the first two columns in Table 10 indicates that communication is not a differentially helpful factor¹¹, since there are negligible differences between the present group and the completed suicides in the prevalence of suicidal communications.

On the other hand, a comparison of the first and third columns in Table 10 suggests a different conclusion. If the comparison is made only with completed suicides who were hospitalized during the year before suicide, those who committed suicide communicated their intent in every instance, as compared with only 56% of the present group. This difference is not statistically significant because of the small number of completed suicides who had been hospitalized within a year of their suicides. However, the addition of more cases may indicate that for hospitalized manic-depressive patients, communication of suicidal intent may be an important factor in pre-

dicting a serious risk of suicide subsequent to discharge. Also remaining to be studied is the important question of the relationship of suicidal communications in a non-hospitalized group of manic-depressives to completed suicide. The next step, therefore, in this series of studies is to investigate suicidal communications in manic-depressives who are not thought to be ill enough to be hospitalized or who refuse to be hospitalized. The study of such a group would give a definitive answer to the value of ascertaining the presence or absence of suicidal communications in predicting the risk of suicide.

SUMMARY AND CONCLUSIONS

1. A study was made of the suicidal communications of 87 patients admitted to a short-term care, private psychiatric hospital.
2. There is a high prevalence of suicidal communications (68%) in such patients.
3. There were 16 different ways of communicating suicidal intent. The most frequent ways were statements by the patient that he wanted to die, that he would be better off if he were dead, that his family would be better off if he were dead, and that he intended to commit suicide. Each of these was made by at least one-third of the patients.
4. The use of suicidal communication as

TABLE 10

COMMUNICATION OF SUICIDAL INTENT IN MANIC-DEPRESSIVE DISEASE :

* Hospitalized in a psychiatric hospital within a year prior to the completed suicide. These 9 patients are part of the group of 60 patients.

[†] Percentages are from informants' reports only (Table 6), since these were the only ones available in the completed suicide group.

a taunt or threat was infrequent, occurring in only 7% of patients. The great majority of communications were, therefore, not perceived as a means of manipulating the environment for ulterior reasons, but seemed rather to be expressions of hopelessness and despair.

5. The suicidal communications tended to be varied and repetitive.

6. The preoccupation with suicide was not a "way of life" for these patients. Over two-thirds of those who communicated suicidal ideas had begun talking about suicide only within one year of admission, and almost one-half within only 3 months prior to admission.

7. Patients with manic-depressive disease showed a much higher prevalence of suicidal communications than did patients in the miscellaneous group.

8. There are frequent references in the psychiatric literature that everyone, or almost everyone, has at some time thought of suicide. It is evident from the findings noted in conclusions 6 and 7 that there is a vast difference between these presumably evanescent and transient thoughts of suicide and the suicidal preoccupations that lead to the suicidal communications described in the present study. These communications do not occur in everybody (in fact, in only one-third of the miscellaneous group, even though they were ill enough to be in a psychiatric hospital) and when they do occur, in the majority of instances they have been present for less than a year. It may very well be that thoughts of suicide in the clinically well persons referred to in the literature are clinically meaningless and unrelated to the suicidal communications and to suicide which may occur in psychiatrically ill patients.

9. It is probable that in patients ill enough to be admitted to a psychiatric hospital those with manic-depressive disease and chronic alcoholism account for the vast majority of patients who make any suicidal communication.

10. There was a high rate of agreement, over 80%, between patients and informants concerning suicidal communications. These

data were obtained by means of a systematic clinical interview in which each question was asked of each patient and informant, and in which all positive answers were explored in detail. The finding of such a high rate of agreement suggests that it is possible to obtain, by means of a systematic interview, reliable and presumably valid information concerning even such a psychologically sensitive area as suicidal preoccupation.

11. There was one category of suicidal communication—the specific statement of intent to commit suicide—that the patients answered affirmatively less frequently than did the informants. Apparently the patients were reluctant to admit to, or did not remember having made, such a specific statement of suicidal intent, although they readily discussed other concerns with death and suicide.

12. The findings in this study of a high rate of suicidal communication in manic-depressive disease and chronic alcoholism are similar to the findings in a group of completed suicides previously studied. It will next be necessary to study ambulatory patients with these illnesses in order to ascertain the value of suicidal communication as an aid in the prevention of suicide.

EXPERIENCES OF A PSYCHIATRIST AS A MEMBER OF A SURGICAL FACULTY^{1, 2}

WILLIAM J. HOCKADAY, M.D.³

The Departments of Psychiatry and Surgery, University of Louisville School of Medicine, are favorably impressed with the value of collaboration in the teaching of general surgery at both undergraduate and graduate levels. This impression is predicated upon the initial success of an exploratory period of integrative teaching of more than two years' duration, during which time a psychiatrist has been assigned full-time to the Department of Surgery.

His participation has been strictly limited thus far to the area of general surgery; that is, it has not included the surgical specialties such as gynecology and orthopedics. The method has been to attend the regularly scheduled clinical conferences, seminars and teaching ward rounds on the general surgery service in the Department's main teaching facility, the Louisville General Hospital. This is a city-county charitable institution with 170 beds for general surgical patients. Approximately 1,200 major and 1,400 minor operations were done in 1958 upon a total of about 2,000 inpatients and 5,000 outpatients on this service.

Every patient on 2 of the 4 general surgical wards has been seen by the psychiatrist for periods which have varied from brief contact during ward rounds to an accrued maximum of 10 hours. Patients on the other 2 wards and from the clinics have been seen only on referral.

Clinical research has been an integral part of the program and has been concerned with certain studies on pancreatitis and delirium, the results however not being germane to this particular report. Basic research concerning the electrophysiological correlates of animal behavior is just getting underway and will offer further opportu-

nities for collaboration with the surgeons in the future. The point to be made here is that the areas of research initially selected have been those more readily appreciated by the surgeon unsophisticated in psychiatry.

The need for an interdisciplinary approach to integrative teaching is intensified by the lack of teachers who have themselves developed a multidisciplinary method. Collaboration of surgeons and psychiatrists in such teaching has previously been only occasional and largely on a part-time basis, although there are a few exceptions(1, 2). Effective communication has thus been limited and this has persisted despite a recognition of the need by such prominent surgeons, for example, as Cope, DeBakey, Elkin, Janes, Moyer and Price(3). Until teachers in these fields come to know and understand each other, their efforts to facilitate the correlation of information in others must result in only a limited success at best.

The concept of full-time collaboration is considered important for the individual members of the two disciplines to best identify with each other and be thus prepared for a more effective exchange of ideas. Titchener and Levine(4) have outlined some of the common grounds of psychiatry and surgery in a treatise directed in part to the surgeon. More research concerning the psychiatric aspects of surgical patients is needed, but the lesson it teaches will require the presence of the teacher.

The objectives and purposes of integrative teaching have been outlined in the Report of the 1951 Ithaca Conference on Psychiatric Education(5). They are implied in the breadth of modern medical science and concern the facilitation of the correlation of knowledge from diverse areas of emphasis. One of the participants in the Conference made the following comment:

... Let us not lose sight of the fact that what is to be correlated is *information*, and

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² This program has been supported in part by U.S.P.H.S. Grant No. 2M-6008.

³ Assistant Professor of Psychiatry and Associate in Surgery, University of Louisville School of Medicine, Louisville, Ky.

not courses, not teachers, not students, not schedules; that where this correlation is to occur, is in the *mind* of someone; that for a student to correlate two facts, he must already possess both facts . . .

We are in agreement with this statement and are of the opinion that medical students, surgical residents and surgeons already have in mind many facts when they come to the clinical discussion concerning their patients. With respect to their psychiatric information, however, there is often a blind spot. Frequently they possess a significant amount of such information but do not trust their observations, fearing that psychiatry is equated with subjectivity and unaware that its data, in many cases, are no more and no less observational than those of other clinical disciplines. Subjectivity is further equated with emotion and, since subjectivity is a bad word, a valuable diagnostic and therapeutic tool accordingly becomes untrustworthy. Emotions are recognized as somehow important, but unscientific, and therefore not capable of being correlated with other data. Furthermore, the process of looking at one's own emotions is recognized as not always a pleasant one.

Although one might characterize the situation in a number of different ways, the most significant problems seem to be those of dualism in the approach to the patient and a certain rigidity in the attitudes of the student or physician towards psychiatry. These attitudes are often colored by denial and by a form of compensation which both obligates and qualifies the individual to form certain opinions of psychiatry which are then applied to the patients. However one characterizes the situation our practical emphasis in teaching would remain unchanged; with a significant amount of information already present, our efforts to facilitate correlation have been just as concerned with attitudes and emotions as with technical and theoretical information. The effort has been to teach primarily in terms of the present and future, with emphasis upon treatment, history taking, the physician-patient relationship and diagnosis by inclusion rather than exclusion.

Two principles have been particularly important in molding our method in teach-

ing. The first concerns our effort to supplement the surgical teaching program without the appearance of doing so by combining parts of two completely separate disciplines. In this respect we have avoided the use of technical jargon as much as possible, and comments and questions concerning any aspect of the patient are encouraged from any source, much in the same way as reported by Early and Gregg(6). When comments are made the effort is directed more toward reinforcing their positive aspects than toward supplying additional data at that particular time. The usual question as to how much is organic and how much psychological has been progressively diminishing in frequency.

The second principle is related to the first in that both have the common aim of preventing dualism in dealing with the patient. It has concerned the role of the psychiatrist and in this respect he has assumed more a role as catalyst than as consultant. Psychiatric consultation from the usual sources has thus continued unchanged. This has not prevented a discussion of these same patients by the psychiatrist in this program. It has, however, helped to avoid a primarily service function rather than one of teaching and it has helped to motivate a wider range of clinical discussion. The implication of this role has been that the psychiatrist was not present only because of the occurrence of overt psychiatric disorders in surgical patients; that he was, in fact, interested in everything pertaining to each patient, though by no means professing to be expert in any field outside his own.

The attitudes of the surgeons have undergone an interesting change since the inception of this program. The psychiatrist was initially faced with skepticism, was then accepted and expected to perform primarily as a psychiatric consultant, and was next placed in the role of internist. At present the clinical discussions are more appropriate to both his multidisciplinary background and his specialty, their content being less oriented toward one facet of the patient to the relative exclusion of others.

The period of initial skepticism was characterized by a sincere politeness on the part of the surgeons, but with little call upon the psychiatrist for comment. Often their

questions, when they did occur, would concern subjects obviously outside the area of psychiatry and which no psychiatrist would logically be expected to discuss even though he knew the answers. This gradually diminished and within 6 months the acceptance of their colleague was symbolized by their offering him an office within their departmental area.

Requests now came with increasing frequency for consultation on patients with overt psychiatric complications. All such requests were met, but with the provision that a concomitant psychiatric consultation be obtained from the usual source and that its recommendations for treatment be followed. Gradually this provision has become routine on the part of the referring surgeons and this routine has persisted despite annual and rotational changes in the house staff. At the same time the reasons for referral have changed. No longer is the presence of psychosis, for example, a sole reason for referral, for now the referral is based more upon an interest in understanding the patient and less to obtain help with a part of the patient that is someone else's business. The traditional and impersonal consultation form is no longer used and the psychiatrist is now asked by the surgeon to see the patient with him.

For a less well-defined and briefer period, the psychiatrist was placed in the role of internist. Although a part of his training had been in internal medicine, he was certified only in psychiatry and took care with the surgeons to stay within the latter role. Despite his lack of definitive response to questions directed to him concerning such subjects as the dosage of digitalis and the effects of transfusion upon tests for sickle cell anemia, the frequency of such questions increased for a few weeks. On one occasion he agreed with the surgeons that the internists had improperly discussed some postoperative syndromes in an interdisciplinary seminar without inviting the surgeons' participation. In the criticism of this;

the psychiatrist's opinion was repeated and its significance reinforced by referring to him as a "certified internist."

SUMMARY

The constant presence of a psychiatrist in a surgical faculty is a powerful motivating force *per se*, and his role in the eyes of the surgeons is of more importance than an active exchange of specific psychiatric information in the successful inception of a collaborative teaching program of this sort. Following such inception an increasing exchange of ideas will take place. The need for such an exchange between psychiatry and surgery is at least as great as is the need for correlative teaching in general.

Some observations of a psychiatrist attempting together with a surgical faculty to meet this need have been described. Our program is young, and there are usually several good ways of doing the same thing. For these reasons, and because of the wide variation in local conditions, we do not offer this report as a model which is necessarily applicable in other medical schools. We do hope, however, that there will be an increasing collaboration among psychiatrists and surgeons in the correlative teaching of surgery.

TRAINING IN PSYCHOTHERAPY : THE USE OF MARRIAGE COUNSELING IN A UNIVERSITY TEACHING CLINIC¹

KENNETH E. APPEL, M.D., HILDA M. GOODWIN, D.S.W.,
HOWARD P. WOOD, M.D., AND EDWARD L. ASKREN, M.D.²

Teaching psychotherapy has many problems. There are too few therapists for too many patients. Treatment methods are frequently based on social and economic status, the availability of teachers experienced in analysis and other factors, rather than on evidence favoring one method or another (8).

One difficulty involves conceptualization. Dogmatic attempts at definition often develop technical jargon, formulae and rituals of procedure employed almost mechanically and automatically. Pseudo-disagreement may occur when therapists employ different frames of reference without realizing it. "Schools" of psychiatry have fought over which level of communication was most important: intrapersonal, interpersonal, or social. The therapeutic effectiveness of various possible interpretations has not been scientifically proven (4). Ideas about "cause" have shifted from the simple cause-effect relationship to "feedback" or "spiral" systems (16).

Another difficulty involves experience. The therapist learns ultimately by treating patients. The beginner is hindered by inexperience, feelings of inadequacy and anxiety. He often feels overwhelmed by the need to explore the depths of the total personality and the complexity of past relationships. He may flounder and compensate by speculation, theory and fantasy. When personality problems are recognized and examined he can learn to treat more effectively. The mechanical use of psychiatric concepts, psychotherapy and stabilized rituals are often monotonously and inappropriately employed. Witness the boring and

unimaginative nature of many case readings. Rigidity stifles the corrective emotional experience (3).

Psychotherapists have attempted to shorten and improve treatment by experimentation. Adler, Alexander, Ferenczi, Rank and Rado are notable examples (2, 3, 7, 14, 15). The time-honored model of a one-to-one therapeutic relationship is yielding at times to a broader point of view. Often the patient is a part of a group of sick people with whom he interacts, in a sort of *folie à deux, trois* or more (5, 10, 17, 19). These people need to be treated too. It is often not advisable to refer these involved persons to other therapists. The literature reports an increasing number of therapists who treat more than one member of a family (1, 6, 9, 11, 12, 17).

Residents, we believe, should see in operation many methods of helping patients. To meet this need, the department of psychiatry of the University of Pennsylvania School of Medicine, has developed a broad and flexible training program which meets residency requirements. Through the Marriage Council of the Division of Family Study of the department of psychiatry, residents may participate in an interdisciplinary graduate program which includes didactic material, group discussion, direct counseling experience with married couples, and individual supervision. The resident spends one day each week for an academic year at Marriage Council. The staff of Marriage Council from time to time present case discussions to the psychiatric staff and regularly attend case conferences.

Marriage counseling is the process through which a trained counselor assists two persons to develop abilities in resolving to some workable degree, the problems that trouble them in their interpersonal relationships (13). A basic assumption is that all individuals grow to greater adequacy and maturity in their relationships if not blocked by such obstacles as loneliness, fear, hostility, guilt and their displacements, or trans-

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Respectively: Professor of Psychiatry and Chairman of Department; Associate in Family Study in Psychiatry; Instructor in Psychiatry; and Resident Psychiatrist, Department of Psychiatry, School of Medicine, University of Pennsylvania, Philadelphia, Pa.

ferences which prevent a person from experiencing the present as it really is and hence behaving effectively. New experience in communication is offered, and a search for more realistic solutions of present difficulties is made in an atmosphere of acceptance and understanding. The process is not encumbered with detailed consideration of conflicts in the past, their devious and disguised transferences, or with intense and difficult ventilations of feeling.

If during the counseling process an individual can experience new understanding of himself and his partner and more satisfying ways of communicating, searching, understanding and behaving, he can often apply these to his family life. Experience has shown that for the marriage problem to be dealt with most effectively, the couple should often be treated as a unit by one therapist (13). The following case treated by a senior counselor illustrates the method used at Marriage Council and the kind of presentation given to psychiatric residents for discussion and learning.

A married couple, referred to Marriage Council by a psychiatrist who knew them socially, were in their early thirties, American born, Jewish, married 10 years with 3 sons. Mrs. Jacobs was 5 feet tall, and weighed 175 pounds. She was affable, dramatic and anxious. She complained of obesity and shock at her husband's sexual rejection in finding her obesity unattractive. She wished that her husband were more "masculine," that they could handle finances more satisfactorily. She feared she had "held the reins too tight."

The husband was short and plump with an amorphous quality. At first he denied marital problems, but soon described a strained atmosphere at home, his wife's unwillingness to let him travel in his job, his inability to say no to her, his fear of his wife's anger, his inability to confide in her, his loss of interest in sex, and his repulsion because of her overweight.

The pair had begun to date in their teens and were married in their early twenties, with both families' approval. Their first child was born by Caesarean section 3 years after their marriage. Though Mr. Jacobs earned \$7,500 per year as an administrator and worked as a salesman on weekends, they had little money for current expenses because of debt.

The wife seemed to be an aggressive, dependent woman still tied to her mother. She was frustrated and angry with her mother's

critical attitude toward her, but was unable to face and deal with her feelings. Though she indicated interest in more sexual activity, there was "something in her that went against it." She had little capacity to postpone gratification and used food as a major source of satisfaction.

The husband was a passive, dependent man. He was hostile in a quiet way, preferring to avoid difficulty. He evaded responsibility by his passivity and had little capacity for self discipline. He showed strength in his education and job achievement, but had low self regard.

Mr. and Mrs. Jacobs were both seen on a weekly basis for 7 months in a total of 24 individual and 5 joint interviews. Initially the therapist concentrated on strengthening Mrs. Jacobs' capacities to deal with everyday life. Mrs. Jacobs' marital problems were intertwined with her difficulties with her mother. As she more adequately handled her mother's interventions in her marriage, her anxiety abated and her self-esteem grew. She began to express resentment about her mother's domination, but added apologetically that her mother "wanted her to be happy or was doing this for her welfare." Mrs. Jacobs realized that when she felt her mother's displeasure she felt a "terrible emptiness," and would eat. After this realization she started to do something about her weight. She had inadequate knowledge of her sexual function and grew up with attitudes that sex was bad, undesirable, and she felt guilty about it. Considerable time was spent clarifying anatomical facts and attitudes about sexuality. She then realized that she had not minded being fat because it made her less attractive sexually, and developed a capacity to confide romantic fantasies to the therapist.

Mrs. Jacobs had felt she had to "make it up to her mother because her father had spent time in prison." In treatment she began to wonder whether her mother had after all been such a victim. She began to recognize that her mother had made the children feel guilty because of her suffering, although she had actually had a part in her husband's offense.

Mr. Jacobs talked about many phases of development. He described sexual experiences, his difficulty in self-assertion and the hostility that underlay his behavior. He brought up his mother's directions of "never answer back, never strike back, tomorrow will be another day."

Mrs. Jacobs had been relating to her husband in the dominating way that her mother had treated her. When her mother made another unreasonable request of her son-in-law, he finally refused, and his wife backed him up despite the mother's rage. Mrs. Jacobs reported

she felt differently after this non-complying expression with her mother and found that she could say no to her without becoming upset.

The couple worked out a financial plan together and assumed more adequate responsibilities as parents. Mrs. Jacobs joined in community activities as an outlet for her aggressive needs and continued to lose weight. At this point counseling was concluded.

A husband and wife with a marital problem precipitated by his sexual rejection of her were seen in a triadic counseling relationship over a 7 month period. The therapist set up an accepting relationship with both, emphasizing their strengths, avoiding sore points. This helped them to be less defensive and enabled them to bring up real issues. The strong participating relationship with the therapist helped the wife to stand up to her domineering mother and achieve insight into her hunger for food. By discovering better ways to handle her day-to-day problems she developed increased strength and self-esteem and became able to assess her attitudes about herself and sex. She could face her disappointments in, and hostility to, her husband and replace romantic fantasy with a real co-operating relationship. She lost weight, became more attractive physically and with the decrease in mutual hostility, there developed affectionate, friendly and cooperative family relationships.

The therapist's encouragement and the new found support from his wife enabled the husband to assert himself against his mother-in-law. Binding together they were able to function as a team in handling their children and other life stresses.

CONCLUSION AND SUMMARY

From the example it is seen that favorable therapeutic results took place without going into multiple details concerning orality and intensive personality analysis.

To illustrate these techniques as they were used in a marriage counseling case, the significant details of a serious interpersonal conflict precipitated when the husband rejected his obese wife, have been presented. Both partners were seen individually and jointly by one therapist. The therapist focused on the day-to-day experience, eliciting the patient's feelings about reality situ-

ations which involved relationships to each other, parents and in-laws. Interpretations were kept to a minimum and were expressed simply, without technical terms. Ego strengths were supported. Ventilation of hostility was kept within tolerable limits. Solutions to difficulties evolved without going into genetics, details of personality structure, or the analysis of oral eroticism involved in obesity. The frame of reference was generally confined to present reality only occasionally moving into the past. The level of communication was interpersonal with occasional intrapersonal accents. The downward causal "spirals" of hostility, alienation, guilt and inadequacy were replaced with upward "spirals" of acceptance, increasing confidence, self-assertion and self-esteem through the corrective emotional experience with the therapist.

This presentation does not imply that detailed microscopic analysis and intensive psychotherapy should not be employed in some cases and the psychiatric residents familiarized with them. Psychotherapy is an inadequately conceptualized subject. It is difficult to teach. Learning should involve a variety of techniques. Residents need experience in experimental enrichment as well as in conventional patterns of psychotherapy. To answer partially this need, training for residents has been provided in the Marriage Counseling Clinic of the Division of Family Study of the University of Pennsylvania.

EXPERIENCES WITH LARGE SCALE INTERHOSPITAL COOPERATIVE RESEARCH IN CHEMOTHERAPY¹

EUGENE M. CAFFEY, JR., M.D.²

The Executive Committee of the Veterans Administration Cooperative Studies of Chemotherapy in Psychiatry has accorded me the privilege of presenting a sketch of the program which has developed during the past 5 years into a series of 5 studies of the effects of phenothiazine drugs upon schizophrenic patients, and of "psychic energizing" drugs upon apathetic schizophrenics and depressed patients.

This series of cooperative studies had its beginning with a conference of representatives from interested hospitals in 1955. Details of the development of an organization for research, the problems that arose in selection of questions suitable for cooperative study, design of methodologically sound, safe and practical protocols, and interpretation of the results of the studies are presented elsewhere(1).

When the program began, the VA Department of Medicine and Surgery had passed through its post-war organizational trials. In its psychiatric services had been created an effective medical care group accustomed to working together in an interdisciplinary fashion. The group was greatly concerned about the impact of what was then the future use of ataractic drugs in the treatment of its patients. Perhaps the existence of such a setting, the challenge of such a problem, and the inspirations provided by administrators and by research-minded outside advisors, are the basic requirements for successful cooperative studies. An initial protocol was devised, and subsequent studies have been designed, through a series of conferences with individuals from the hospitals attending on a voluntary basis, aided by representatives from many ancillary services and statisticians. Final decision as to participation in

each study has been the prerogative of each hospital and its management.

How large scale have been our cooperative efforts? Figure 1 shows the location of each hospital which has participated in at least one study. We have had from 27 to 37 hospitals in each study; the patient populations have varied from 404 to 805. In the first two studies some 6,000 comparisons between drugs on criterion and background variables had to be computed; in the third 1,080 comparisons were made. Such computational loads, of course, required planning for the use of high-speed computers for data processing. Practical, but manageable problems in communication arose from the geographical spread, the size of populations studied, the presence of a rich variety of points of view in the multitude of observers, and the awesome amounts of data that had to be winnowed for meaningful conclusions. The circumstances presented a severe challenge to the reputed efficacy of the study drugs.

We have now completed 4 studies, are engaged in a fifth, and planning the sixth. All have involved a centralized randomization of the studied population by hospital units and have been of the double blind type. The efficient willing cooperation of the pharmaceutical firms has made it possible for us to give all medications orally in identical capsules. The prime instrument of evaluation has been the Multidimensional Scale for Rating Psychiatric Patients (MSRPP), commonly termed the Lorr scale, although we have used a number of other devices in the studies. We have especially attempted to record laboratory findings and clinical evidences of side effects in a way allowing for summarization. The size of our patient populations has made it possible to use powerful statistical methods, particularly the analysis of covariance, and to investigate something more than 25 variables simultaneously in each study.

The first two studies, in 1957, were linked into one articulated study(2). The first in-

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

volved a comparison of chlorpromazine and promazine, in fixed dosage over a period of 3 months, in the treatment of acute and chronic schizophrenic men, with phenobarbital and an inert material for control substances. The second study was a "cross-over" type of extension involving treatment for a second 3 month period of a majority of the patients in the first study. Study III, in 1958, was a comparison of the effects of chlorpromazine, perphenazine, prochlorperazine, trifluoperazine, and mepazine, on newly admitted schizophrenic men, with phenobarbital as a control substance⁽³⁾. The drugs were administered for a total of 3 months, in fixed dosage for the first month, and in a flexible dosage pattern for the remainder of the study. The fourth study, in 1959, now in the analysis stage, involved an examination of the effectiveness upon chronically ill schizophrenic men on a maintenance regimen of chlorpromazine, of a combination of a fixed dose of chlorpromazine and one of the "psychic-energizing" substances (isocarboxazid, imipramine, dextroamphetamine or trifluoperazine) with an

inert substance as a control. The energizing drugs were administered for a total of 5 months, in fixed dosage for the first month and in a flexible dosage pattern for the rest of the time. The fifth study, now underway, is designed to examine the effectiveness of "psychic energizers" (isocarboxazid, imipramine, dextroamphetamine with amobarbital), again with a control inert substance, in anti-depressant application, with both men and women. Again there is an initial fixed dosage plan, followed by flexible dosage for the major portion of the treatment time of up to three months.³

The results of the studies completed⁴ will be published in appropriate professional

³ The generic and trade names of drugs referred to are: chlorpromazine (Thorazine), promazine (Sparine), perphenazine (Trilafon), prochlorperazine (Compazine), trifluoperazine (Vesprin), mepazine (Pacatal), isocarboxazid (Marplan), imipramine (Tofranil), dextroamphetamine (Dexedrine), trifluoperazine (Stelazine), dextroamphetamine with amobarbital (Dexamyl).

⁴ Detailed information can be obtained by writing the Central Neuropsychiatric Research Laboratory at Perry Point, Md.

FIGURE 2

Mean Total Morbidity Scores After 6 And 12 Weeks of Treatment

journals, but by a brief mention of some of the results we shall illustrate their form. Necessarily the language in which the results are expressed is derived from the measuring instruments and the method of analysis. We are using the most comprehensive single criterion: the total morbidity score derived from the Lorr scale. A decrease in this score is equivalent to a reduction in symptomatology. In study one, chlorpromazine was shown to be superior to promazine in the over-all reduction of symptomatology as illustrated in Figure 2. Incidentally, all differences discussed are statistically significant at or beyond the 5% level of confidence. In study II (Figure 3) it is apparent that this superiority was maintained if treatment were continued for a second 3 months. Figure 4, based on the third study, shows that 4 phenothiazines: chlorpromazine, prochlorperazine, trifluorpromazine, and perphenazine, were demonstra-

bly more effective than one, mepazine, although all 5 were clearly superior to phenobarbital in reduction of total morbidity. There were no significant differences among the 4 more effective drugs, even though the difference shown between prochlorperazine and trifluorpromazine may appear, on the graph, to approach significance.

There is another way in which we can present, generally, findings from these studies of phenothiazines. The Lorr scale is broken up into 11 factors, each representing symptom clusters. In Table 1 are shown the effects of phenothiazines on the Lorr factors, as compared with phenobarbital. The left side of the table shows the results from the first study and the right hand side from the third, each dealing with a different population of schizophrenic men. The first 3 factors are shown to have been altered in a significant way by all of the phenothiazines. The rest of the chart shows the factors upon

which a given drug was more effective than phenobarbital. Some differentiation in areas of drug effectiveness becomes apparent as the list is descended.

Additional methodological studies have included a study of agreement between raters using the Lorr scale which yielded for total morbidity an interclass correlation of .82(4); and a determination of whether the change in clinical condition during the course of study III was due to any of the control variables (age, marital status, duration of illness and so on). A summary of the laboratory findings and side effects experienced in study III has been prepared, showing the inherent variability in a schizophrenic population against which current deviations possibly due to drug effects must be evaluated(5). This summary shows no serious side effects to have been experienced, and a relatively low incidence of Parkinsonian-like symptoms, other clinically evident side effects, or laboratory abnormalities. An examination of the weight gain in each drug group has been carried out because of the problem described by Planansky arising from the use of "tranquilizing treatment on a mass scale, namely, obesity on an epidemiological scale"(6). Figure 5 shows the average change in

weight over 3 months for each drug group, and phenobarbital, in studies I and III. It will be noted that all of the groups receiving phenothiazines gained weight. Specifically, the groups on chlorpromazine gained an average of 7 to 8 pounds, whereas the group on promazine gained an average of 4.5 pounds, and the group on mepazine gained an average of 2.5 pounds.

As the program has progressed, there has been continuing assessment of the value of the measuring devices, and consideration of methods for their improvement. Most importantly, employment of the Lorr scale by a large number of psychologists, psychiatrists, and nursing personnel in a clinical setting resulted in many suggestions for its improvement. During the summer of 1959, with the cooperation of the staffs of the hospitals and with the assistance of the Central Neuropsychiatric Research Laboratory, a revision was designed and developed in the Neuropsychiatric Research Laboratory of the Veterans Benefits Office in Washington. This revision led to an interview scale, the Inpatient Multidimensional Psychiatric Scale (IMPS), which, together with a new ward observation scale, the Psychotic Reaction Profile (PRP) developed meanwhile by Dr. Lorr, was put into use in our fourth and

FIGURE 5

Weight Changes With Phenothiazine Treatment

fifth studies. It is expected that out of this testing will come a greatly improved instrument for patient description and for measurement of treatment effects. Besides improving the old, we have recognized with increasing clarity the need to account for the possible significance of the attitudes of staff and patients on the demonstrated effects of the drugs. In the fourth and fifth studies we have introduced scales designed to produce information about the attitudes of psychiatrists, clinical psychologists, social workers, nurses, nursing assistants, and patients toward mental illness, and towards the applicability of chemical methods to its treatment. In the fifth study, we have introduced, too, a follow-up step with the hope that we will be able to learn something of the natural history of depressions and the extent to which beneficial effects of treatment may persist.

The existence of the cooperative studies has, as it was hoped, engendered concomitant studies of the cooperative study pa-

tients by individual hospital investigators. These have included examinations of electroencephalographic changes, drug excretion rates and psychological effects. These smaller specialized studies have broadened the scope of the investigation of the role of chemotherapeutic agents in mental illnesses and provided suggestions for more detailed investigation.

The studies have been truly cooperative, devised and executed by the investigators who are responsible in each hospital for their completion; coordinated through an executive committee; and operationally controlled by the Central Neuropsychiatric Research Laboratory which supervises the randomization procedures, prepares the forms and manages the planning and execution of the analyses. Working together in this way we have been able to reduce the lead time in the production of studies from 1½ years to 6 months, and have been able to devise and execute increasingly complex and sophisticated studies while maintaining

flexibility and an attitude of venturesome inquiry. We have shown that the phenothiazine drugs are effective in reducing the symptomatology of schizophrenic patients and that there is no difference in the effectiveness of one as compared with another of four of those drugs examined in our study III. The program has provided reliable information about the drugs and about new methods and measures to the profession at large, and has stimulated research interest and developed better informed habits of observation among our personnel.

THE CLINICAL SCREENING OF PSYCHOPHARMACOTHERAPEUTIC AGENTS: A CONSIDERATION OF METHODOLOGY¹

JAMES H. EWING, M.D., KARL RICKELS, M.D., AND
HAROLD H. MORRIS, M.D.²

The initial screening of psychopharmacotherapeutic agents is an important area of research in psychiatry. It has received little focused discussion in the literature from the standpoint of general approach and methodology. The authors propose to describe and comment upon one approach to problems confronting the investigator in this difficult area in which generally accepted standards of control often must be sacrificed in order to assure maximum safety of the patient and in order to minimize the chance of overlooking subtle or even obvious leads. While many have accumulated far more experience than we in drug screening, we wish to call attention to certain aspects of a program which offers some unusual advantages and opportunities for this type of research activity.

FUNCTIONS OF A PATIENT DRUG SCREENING UNIT

For initial orientation, certain basic functions of a drug screening program might be proposed. These include:

1. The detection of agents which have one or more unique properties of human pharmacological action, an influence upon special mental functions or a normalizing effect upon abnormal mental states or symptoms.
2. The screening out of agents which are inactive or which produce undesirable side effects.
3. The presentation to pharmaceutical companies and other laboratories of preliminary data on a wide range of routine observations of biochemical, physiological and psychological actions, dosage range and clinical psychiatric effects, as well as special leads uncovered in any of these categories.

These data must be rapidly transmissible in standardized form and in readily understandable terms to both drug firm and clinical investigator. Out of the chance observation of the preliminary study can come important hypotheses for definitive test and later better controlled clinical experiments.

DESCRIPTION OF FACILITIES AND MILIEU

In order to set forth a number of our views concerning methodology, it is necessary to sketch briefly certain features of our own set-up which differ from those of many other workers.

Our research facility is located on an 85 bed inpatient psychiatric service of a 3 year old community general hospital in the city of Philadelphia. This service and our research unit have been in operation since the opening of the hospital. The service functions as an inpatient teaching and research center of the Department of Psychiatry of the University of Pennsylvania which is located close by.

The patients come to us from a predominantly lower and middle class socioeconomic urban environment.

The psychiatric service provides short term therapy. The treatment orientation throughout the service is best described as eclectic. Therapeutic approaches of the regular and visiting staff represent a wide range from group and intensive psychoanalytically-oriented psychotherapies to standard physiological treatments.

The general milieu of the service reflects a high degree of patient participation in the day to day policy making and administration. Throughout the service there is no segregation by race, age (adolescence through old age), diagnosis, nor sex (except for separate dormitory space).

The research unit occupies ample space within the physical boundaries of the service.

¹ Read at the 115th annual meeting of The American Psychiatric Association, Philadelphia, Pa., Apr. 27-May 1, 1959.

² Department of Psychiatry, University of Pennsylvania and the Mercy-Douglass Hospital.

PERSONNEL

The key members of the research unit staff are full-time in investigative work. They include 2 psychiatrists, a research nurse and an experimental psychologist. The day to day evaluative service of all first year residents and most of the regular clinical staff are also called upon in our drug screening procedures.

ADVANTAGES AND OPPORTUNITIES OF THIS TYPE OF SERVICE FOR PRELIMINARY DRUG SCREENING

Provided certain difficult problems of control can be worked out, we feel that the type of facilities, milieu and personnel described offers certain advantages and special opportunities for effective patient drug screening. In the first place, acutely ill psychotic subjects provide an experimental population which tends to include wider individual ranges of gross psychopathology, patterns of illness less complicated by hospitalization and other therapies and greater responsiveness to therapeutic intervention than chronic hospitalized patients. There is evidence that responses to drugs depend in large measure upon the interaction of drug and numerous other variables difficult to identify, let alone control adequately. It seems justifiable to take the position that subtle drug effects are most likely to occur and, with appropriate procedures, may be best observed on a relatively small, eclectic and intensive treatment service where the features of hospital management, vicissitudes of ward life and amount of attention by personnel are somewhat equated among research subjects, and between them and service patients. Such a service with its heterogeneity of population characteristics and *laissez faire* milieu allows, and indeed calls forth, a wide range of adjustmental behavior for inspection. This is in contrast to the situation on a static and highly structured ward of chronic hospital patients.

A second advantage is the opportunity for intensive and nearly continuous individual surveillance of a relatively small number of subjects (our unit functions most efficiently with 10 to 15 subjects under test at one time).

Multiple independent observers, studying the same phenomena with the same

measuring devices and by similar standards, heighten objectivity and help to circumvent individual blind spots.

The cross checking of phenomena by observers of different professional backgrounds and training, whose self-conceived and actual roles in the hospital life differ, also serves to minimize experimental bias.

The conception and development of such a drug testing operation as a permanent and continuing one provides for the accretion of relevant experience by all involved. This enhances efficiency of both clinical and research personnel. In the case of our own unit, the daily personal interaction of research and clinical staff, the sharing of tasks of observation and the assumption by the research team of some responsibility for patient treatment seem to have minimized the problem of witting and unwitting sabotage of research efforts by clinical personnel. This contrasts with the consequences of introducing special research projects onto an established and structured ward by outside research personnel, thus disturbing accustomed routine.

The effective utilization of the above described facilities, milieu and personnel is dependent upon such matters as methods of evaluation, selection of experimental population and experimental design. We propose to discuss these in the light of our own experience and efforts.

METHODS OF EVALUATION

A variety of evaluation techniques and measures have been tried. Our present battery includes the following:

1. Laboratory tests.
2. Routine physiological measurements.
3. A physical sign and symptom checklist of 50-odd items. This is supplemented by additional information from daily rounds.
4. A ward observation-behavior rating scale which measures 4 degrees of deviation from the presumed norm in a number of items. The items are grouped into categories and subcategories of behavior on a scale from noninterpersonal appearance and behavior to interpersonal and intragroup behavior.
5. A quantitative mental status form used

in the context of an unstructured clinical psychiatric interview.

6. A 4-point scale of overall improvement.

In the construction of these tests, special effort has been made to define, standardize and group terms so that their meanings are discrete, consensually valid among our own group and are part of the working vocabulary of most psychiatrists. We suggest that often too little attention is paid to this obvious matter.

In addition to the above measures, one standard rating scale which has been subjected to extensive reliability testing is utilized. We currently employ the Lorr Scale. Finally, scales and checklists are supplemented by the clinical notes of all observers.

FUNCTIONS OF INVESTIGATIVE TEAM

The team functions are divided in the following way. One senior research psychiatrist serves as pharmacotherapist. He assumes responsibility for all matters of patient management relative to the therapeutic trial. Both he and the research nurse on independent daily rounds make ratings and clinical notes. The full-time status of the research nurse allows her to collect and record all data and to oversee the management of all patients as prescribed by the physician. Her notes and ratings are supplemented by those she routinely collects from ward nurses, attendants, occupational and recreational therapists. She spends up to 4 or 5 hours a day in direct personal contact with patients as they go about their daily activities and with the clinical staff.

The resident physician in charge of each patient is also responsible for independent evaluations which are subsequently discussed with him in preceptoring sessions.

It is possible to combat bias by applying the double-blind technique to the weekly evaluations of the second senior research psychiatrist.

In the assignment of functions, additional control is introduced through the provision that all categories of data be evaluated independently by at least 2 members of the investigative team.

SELECTION OF EXPERIMENTAL POPULATION

All patients who are selected by the clinical staff for drug therapies are available for our studies.

A. Subjects for Initial Trial

Approximately 5 patients are selected for the unhurried and individualized exploration of specific drug actions over the lower limits of therapeutic dosage range, using oral medication. Special criteria of selection for these subjects include: age between 21 and 45 years, a minimum of 2 to 3 months residence on the service, previous participation in a drug study, chronic illness (over 3 years) with failure to achieve social remission, cooperativeness and ability to report subjective symptoms.

B. Subjects for Therapeutic Evaluation

When some idea of relationship between dosage range and effects has been obtained, 25 to 30 additional subjects are used for therapeutic trial.

Approximately 2/3 of this group are selected on the basis of a duration of present episode of illness (not necessarily total duration of illness) of not over 1 year. Although similarity of diagnosis according to official APA nomenclature does not insure homogeneity in terms of drug influenceable variables, this portion of the test group is selected from one major diagnostic category chosen for likely responsiveness to the agent under test. It has been felt that this procedure does facilitate the simultaneous comparative observation of patients.

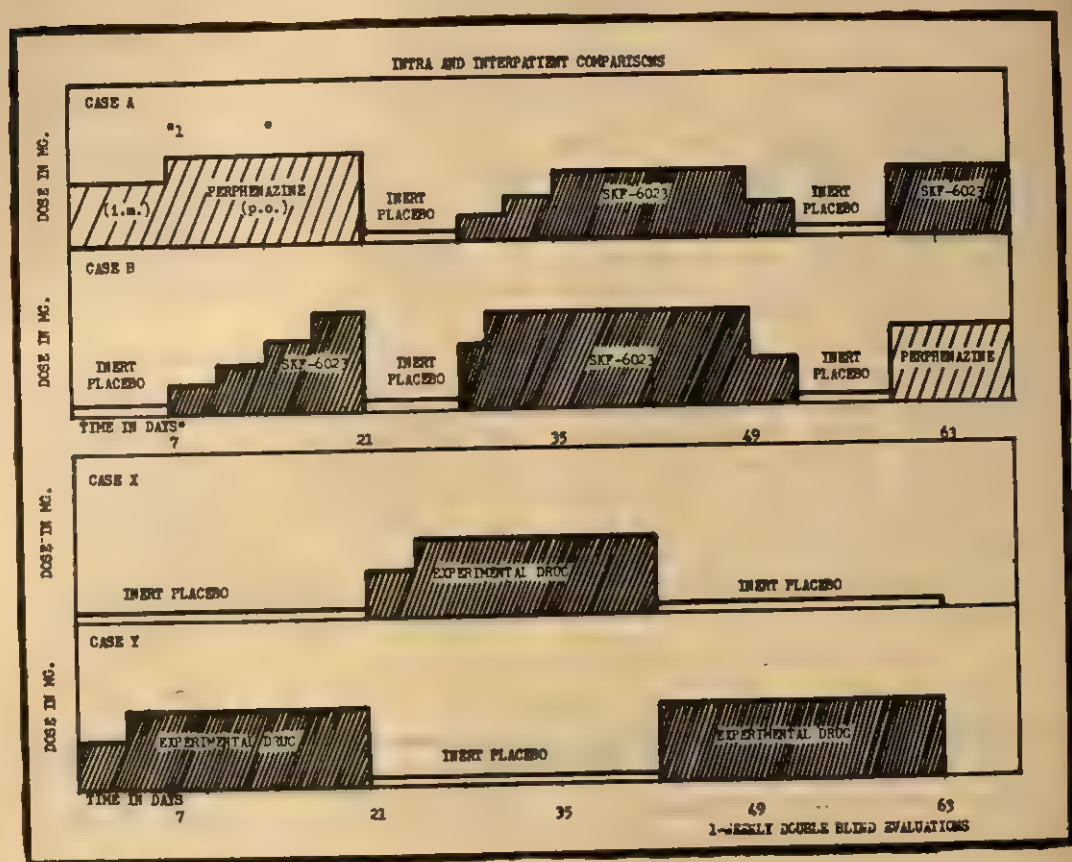

An additional 1/4 to 1/3 of the therapeutic trial group is selected on the basis of common characteristics (target symptoms) such as disorientation, or hyperactivity, upon which the influence of the drug seems to be of special interest.

EXPERIMENTAL DESIGN

Our experience has convinced us of the advisability of studying all experimental drugs against an active standard referent agent and against inert placebo. Care in the selection of this active drug is important. A number of criteria for its selection have been found helpful.

In the preliminary evaluation of an experimental drug against inert placebo and

FIG. 1

standard referent agent it is possible to utilize both inpatient and outpatient "and between patient" comparisons in order to enhance the objectivity and scope of data.

Figure 1 gives medication schedules of 4 cases simultaneously under observation. It illustrates some of the comparisons that can be made. Among others these include in the same patient:

1. Comparison of response patterns to experimental drug following initial and subsequent inert placebo intervals.
2. Comparison of short trials on experimental drug with those on standard referent agent.
3. Comparison of experimental drug effects over a range of doses.
4. Comparison of double-blind observations made at weekly intervals.

Certain simultaneous interpatient comparisons are also possible through the appropriate manipulation of dosage schedule

and of drug conditions. Examples are comparisons of:

1. The effects of standard referent agent in one case against effects of experimental drug in another case.
2. The responses to therapeutic doses of experimental drug in different cases.
3. The effects of equivalent body weight doses of experimental drug.

It is obvious that in this type of experiment only relatively acute effects can be observed and that such short inert placebo trials limit the conclusions which can be drawn from the data, especially using subjects with illness of short duration under the influence of an intensive treatment-oriented milieu. Quantitative comparisons can only be rough estimates for other reasons too.

As experience and number of cases in a particular series accumulate, it is frequently possible to improve the quantification of

observed drug effects through changing from a flexible to a rigid dose schedule and to a formal crossover design (Figure 1).

HANDLING OF DATA

In the authors' experience, one of the major problems in this type of work, generally of less concern to those in other clinical research activities, is the systematic handling of data during the course of an experiment. The strategy of conducting a study so as to uncover, exploit and check on promising leads, and a continual need for close inspection of data to insure safety and efficiency, require that a number of types of accumulated individual patient data be readily available from day to day. Also, one is frequently called upon to provide information to a sponsoring drug firm or must share information (such as dosage range explored and side effects) with other investigators.

Although each worker will have his own preferences and ideas as to how to cope with the problem of maintaining up to date summary data at his fingertips, a reproduction of an individual patient record used by the authors appears in Figure 2. This is presented more to underscore the above points than to make recommendations about "how to do it." This illustrates the graphic method which we have finally settled upon for maintaining case data in a form which permits the rapid establishment of significant relationships.

With this method of representation of data, certain psychiatric changes and physiological signs and symptoms can be correlated with each other and each with drug dose-time parameters. Of course, the major problem in using such a system is familiarizing oneself with the lengthy code in which each letter and number refers to a particular item of one of the rating scales or checklists.

REPORTING OF DATA

Figure 3 is presented to emphasize the importance which we see in making available detailed individual summary data for drug firm or clinical investigators, since others may want to seek clues as to a possible significant relationship.

The reporting of overall as opposed to individual summary data in preliminary psychiatric drug testing is the subject of another paper in preparation and will not be considered here.

GENERAL COMMENTS

The authors are mindful of the fact that there are numerous limitations inherent in the general approach to preliminary drug screening which they have presented. For example, long range therapeutic and toxic effects cannot be assessed. An experimental sample of 30 to 35 patients is not large enough to guarantee detection of all acute therapeutic or side effects. The fact that a large percentage of acutely ill patients improve irrespective of whether or not a drug is employed, especially on an active treatment unit, is not entirely compensated for

by careful attention to problems of methodology.

It might be suggested that for this type of preliminary study the authors go too far in attempting to apply quantitation to their observations. Whether or not this is the case, it does serve to encourage care and specificity of observation.

Finally, in our own case, the type of program described is part of a larger research effort. This leads us to comment that the type of preliminary screening activity described in this paper can be incorporated into an investigative program in such a way that it contributes to other types of clinical research.

SUMMARY

1. The methodology of the initial patient screening of psychopharmacological agents is a relatively neglected but important area for discussion and improvement.
2. The main functions of this activity are to uncover safely and efficiently a wide variety of leads about desirable and undesirable pharmacological and psy-

chiatric actions. This requires balance and compromise between the practice of the clinical art of pharmacotherapy and the use of procedures of good scientific control.

3. There are advantages in conducting such investigations on a research and teaching-oriented, active and eclectic treatment, inpatient service, using small numbers of acutely ill psychotic patients under intensive observation for periods up to 2 to 3 months. Subtle drug effects can be seen, and such a milieu calls forth a wide range of adjustmental behavior for study.
4. Multiple observers of different professional backgrounds and training, using a variety of rating scales and checklists to evaluate independently the same phenomena, enhance objectivity, diminish bias and help to circumvent individual blind spots.
5. There are special problems of selection of subjects since one is interested in observing the effects of drugs upon a large spectrum of psychopathological factors while insuring safety.
6. In the experimental design the testing of a new drug against a carefully selected active referent agent and inert placebo, and the use of inpatient and outpatient comparisons are feasible and to be recommended. Although starting with flexible adjustment of dose, a rigid dosage schedule and true crossover design can be employed to advantage safely in the later stages of many studies.
7. Along with the collection of data by open experiment, provision can be made for employing double-blind technique.
8. There is a special need in preliminary drug testing for systematic handling of individual case data during each investigation in order to uncover and exploit leads, insure safety and to allow for the report of certain kinds of summary data to drug firms and to other investigators.
9. The detailed post-experiment report of individual case data allows others to seek significant correlations other than those of interest to the investigator himself.
10. This particular kind of research can be effectively incorporated into a larger research program.

PSYCHIATRIC FACTORS IN MEDICAL STUDENTS IN DIFFICULTY: A FOLLOW-UP STUDY¹

RAYMOND W. WAGGONER, M.D., Sc.D.,² AND
THORNTON WOODWARD ZEIGLER, Ph.D.³

For years there has been increasing interest in the methods which can be used in the selection of persons for various types of activity: the military service, industry, and professions. In some medical faculties, there has been a desire to develop more knowledge about the relationship of student personality adjustment and medical school success. Of particular interest are the intellectual and personality characteristics of an individual who could and should become a qualified physician. For over 20 years psychiatrists and psychologists from the Department of Psychiatry of the University of Michigan Medical School have carried out a program of systematic evaluation of medical students who present problems as a result of either scholastic or social difficulty. Also evaluated are those applicants whose credentials or regularly scheduled interviews raise questions regarding admission. An earlier paper presented in 1946 described the program being carried out at that time and some of the problems (1). The present paper is a description of the development of this program with a follow-up on students referred during the 3 years 1943-1945.

Early in the program the number of students referred for evaluation was relatively small. Most of the students were examined by the authors. Under such circumstances, it was possible to establish a uniform method of evaluation and for the psychologist and psychiatrist to discuss each student before making a final report to the Medical School administration. Students were referred for various reasons, such as scholastic difficulty, social and family prob-

lems, and even for a brief therapeutic session concerning his reaction to being requested to withdraw from school.

The most frequent reason for referral has been an unsatisfactory scholastic record or unacceptable behavior. Occasionally the student has come to the psychiatrist himself, or has asked for such referral. As the administrative staff of the Medical School and the members of the Promotion Board began to develop more confidence in the techniques being utilized, there was a progressive increase in the number of students referred for evaluation. This increasing load required more than the original psychiatrist and psychologist. Inevitably this led to variations in the reports. For example, a few of the psychiatrists felt that it was unwise or unnecessary to utilize psychological studies and for a time many of the students who were referred for psychiatric evaluation had no psychological study. Even after a definite policy had been established in which all referred students were to have a psychological study, the psychiatric reports varied somewhat in accordance with the psychiatrists making them. These variables have made it difficult to develop a valid report.

Certain philosophical questions present themselves for consideration. For example, in our material are a number of medical students who were doing satisfactory work from an academic point of view but who had made a poor adjustment with their associates or had presented serious social problems. Psychological and psychiatric evaluations proved some of them to be seriously schizoid or even schizophrenic. Since such a student may do satisfactory academic work, we are faced with the dilemma of the propriety of allowing such a student to graduate. The Medical School would seem to have an ethical responsibility in this matter. On the other hand, there are well-adjusted students whose intellectual ability, reading ability, or capacity for

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

³ Assistant Professor of Psychiatry, The University of Michigan Medical School, and Chief Psychologist of the Neuropsychiatric Institute.

concentration is such that they do marginal or unacceptable academic work. The question is immediately raised as to whether these students should be given sufficient assistance to do acceptable academic work, or whether they should be dropped because of failure to meet basic scholastic requirements.

In order to make an evaluation of our recommendations to the Medical School, we have reviewed the records of those students or applicants who were seen over

the 3-year period noted above. Figure 1 shows our experience with 13 applicants. Two whose admission was recommended went elsewhere; one of these is now an assistant professor of psychiatry. One applicant, who was considered of high intellectual capability but who appeared to be somewhat immature and emotionally inflexible, and in whom there was a question of adequate motivation for the study of medicine, was recommended for acceptance with hesitation but was later dropped be-

FIGURE 1
MEDICAL SCHOOL PROGRESS OF 13 APPLICANTS
PREDICTION

○ Indicates the students recommended who did not enroll here but graduated elsewhere.

cause of inability to meet scholastic standards. Another student was considered immature, unstable and with a paranoid reaction. Against strong advice, he was admitted, had serious difficulty during the freshman year and was dropped because of an unsatisfactory scholastic record in his second year. Included also are 4 applicants who were referred before being accepted because of questions raised during the pre-admission interview or because of inadequate preparation or borderline scholastic records. These were all recommended for admission. Of these 4, one graduated as fifth in a class of 132 and is reported to have been an excellent intern. One graduated 23rd in a class of 92, was considered to be an unusually good intern, and an excellent resident. Two graduated in the lower third of their class but have made satisfactory records subsequent to graduation. One pre-admission student with high intelligence but with questionable vocabulary and reading ability, whose Rorschach report suggested that he was striving beyond his capacity, was given a poor prognosis, as decidedly borderline, and likely to fail. He was admitted and eventually graduated 74th in a class of 107. As an intern he did good work, was considered cooperative, pleasant and intelligent. He is now an assistant professor in a medical school and considered to be an exceptionally well-qualified physician. Of 4 other applicants of whom we recommended 2 for admission and suggested rejection of 2, there is no further record.

The 18 students who were seen because of scholastic difficulty after their admission to Medical School are shown in Figure 2. Three who had been dropped but were readmitted on our recommendation all completed Medical School with somewhat below average records. Each of these students was given advice and support and all functioned satisfactorily as interns. Fifteen students were referred for scholastic difficulty before the problem had reached the point of dismissal. Included are 5 students who were considered unlikely to be able to complete their medical school career because of personality difficulties or lack of motivation. These students were eventually dropped because of inability to do satis-

factory scholastic work. All but 2 of the remaining 10 had significant emotional problems, with which they were given some help. The other two were considered to be overly sensitive but otherwise had no significant emotional problems. All of these were kept in Medical School on our recommendation. These students were rated scholastically at the time of graduation in the lower third of the class, with the one exception, whose record was mid-class level. With one exception for whom we have no record, these graduates were reported as doing satisfactory to excellent work as interns and/or residents.

In evaluating these findings it appears that the ultimate success or failure correlates moderately well with our clinical and psychological prognosis. Such a study necessarily raises interesting philosophical conjectures. It would be of value to establish not only college credit requirements but personality and intellectual characteristics in order to qualify for the study of medicine. Craig has said that an "individual should have a desire to be of service to humanity and have scientific inquisitiveness. He should have basic intelligence, good judgment, sympathy, tolerance, honesty and humility" (2). Macnamara indicates that the virtues of a good doctor are "goodness, kindness, patience, unselfishness, humility, reliability and cheerfulness" (3).

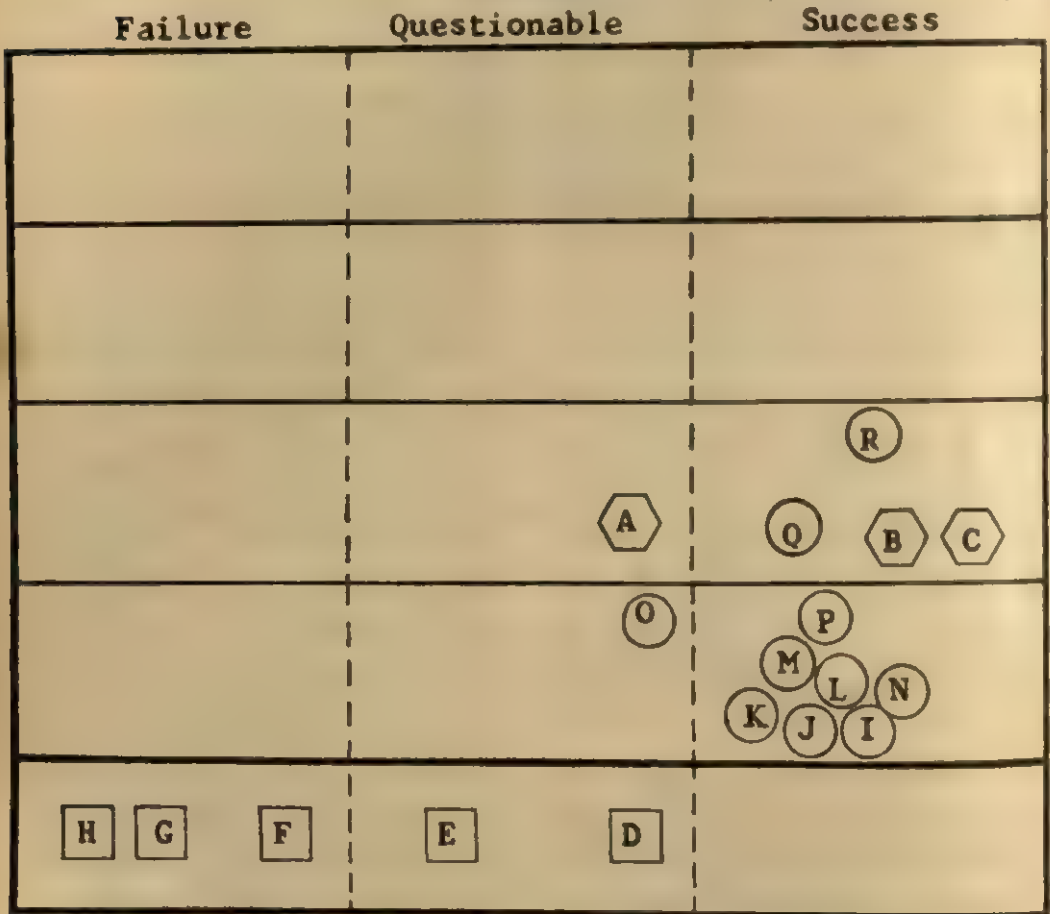

Some of the characteristics of the good physician which might be listed are honesty and sincerity, integrity, sympathy, tolerance and understanding, dedication, motivation associated with a real interest in people. It is essential to have enough self-knowledge to avoid involvement with the patient to the point of causing iatrogenic illness. Few persons would quarrel with these characteristics as qualities which should be possessed by the physician. The problem is the extent to which the Admissions Committee should insist upon the presence of these characteristics or of such factors as a high level of intelligence or of scientific inquisitiveness.

In a study of the relationship between potential predictor and criteria of performance of medical students, Dr. Lowell Kelly, Chairman of the University of Michigan Department of Psychology, and co-workers developed a number of predictor variables

and criterion measures(4). From their study it appears that there is little agreement among alternative criteria in reference to internship ratings. Interestingly enough, a variable considered under the title, "Over-All Promise," was not signifi-

cantly related to any of 200 predictor variables. There was little correlation with any medical school grades or with state or medical board exams. However, there was a surprisingly high correlation with sociometric ratings made by peers in the senior

FIGURE 2
MEDICAL SCHOOL PROGRESS OF 18 STUDENTS REFERRED BECAUSE OF
ACADEMIC DIFFICULTY
PREDICTION

-  Students with relatively mild emotional difficulties.
-  Students who had been dropped and were readmitted.
-  Students who had severe emotional difficulties or were poorly motivated.

year. It is interesting how few of the internship ratings are associated with ability scores or with indices of scholarship. Dr. Kelly, in a personal communication, states that by all odds the best predictor of internship rating are strong vocational interest scores on tests administered before admission to Medical School.

CONCLUSIONS

1. A student evaluation and assistance program of the sort referred to here functions most satisfactorily if the number of psychologists and psychiatrists are sharply limited, and if they work together as a unit with the Admissions Committee and the Promotion Board.

2. Prognostic evaluations based upon such studies appear to be relatively valid.

3. More attention should be paid to personality characteristics and to motivation in the selection of students for the study of medicine.

4. Research should be undertaken to determine those factors which correlate best with success in the field of medicine. An example of such research is that which has been done by Dr. Lowell Kelly and his associates. This type of investigation should be continued and amplified.

EVALUATION OF EMOTIONAL DISTURBANCE IN 403 ISRAELI KIBBUTZ CHILDREN¹

MORDECAI KAFFMAN, M.D.²

For a little more than 40 years, the Israel communal settlement called Kibbutz (plural, Kibbutzim) has carried out a very unique program in child-rearing. In these settlements, partly for objective and partly for ideological reasons, children are brought up from birth in separate children's homes. They are reared by trained nurses in groups of 6 children of equal ages which are merged into larger groups numbering 12 to 18 when they reach the age of 4. This group of age-mates remains rather constant in size and composition throughout the years from kindergarten through high school.

During the first half-year of life, although the infant lives in the children's house, the mother-child relationship very much resembles that of the traditional family. The baby experiences the mother in terms of daily routine as a source of gratification and safety. The usual maternal functions such as feeding, cleaning, handling and fondling are mainly performed by the mother. Most of the infants are breast-fed unless there is a clear-cut medical contraindication. The nurse, during this period, takes care of the management of the infant's house and gives guidance to the mothers. Later on the nurse gradually takes over the care of the child and at the end of its first year she is wholly responsible for it. Usually by this time the process of weaning has been completed. During the first half of his second year the child leaves the infants' house to go with his group to the toddlers' house which is designed to hold a maximum of 6 children. A new nurse and aide take care of him during the day-time. The nurse is not only concerned with the physical care, emotional needs, and well-being of the children in her charge, but has also a decisive role in discipline and social areas. She trains the children in self-feeding, toilet habits, independ-

ence, and group interaction. Therefore, the nurse assumes functions and duties usually performed by the parent in Western society.

As already mentioned, during the first half year of life and gradually less in the second half, the child is in close contact with his mother. From the second year he is with his parents in their room daily in the two or three hour interval between the parents' return from work and the child's bedtime. On rest days the child spends almost the whole day with his parents. The time that children and parents are together is absolutely child-oriented. The nature of parent-child interaction depends naturally upon the ages of the children. These hours are generally used as the child wishes: playing, reading, taking a walk. Both the father and the mother are equally active in sharing their time with the children.

The question whether the Kibbutz system of education may be considered as a variety of "maternal deprivation" has been raised by Bowlby(1) and Caplan(2), as well as in the special workshop devoted to this problem at the 1957 annual meeting of the American Orthopsychiatric Association(3). Unfortunately very little reliable data had been collected to corroborate "clinical impressions" about how much the Kibbutz child fits or deviates from the so called normal standard. Among difficulties to be overcome we may mention the choice of variables to be investigated; the criteria to be adopted in quantifying human behavior; and the way of obtaining information from the child's environment. Moreover, since very few attempts have been made to study the behavior of unselected groups of "normal" children, it is rather difficult to compare symptoms and behavior of Kibbutz children in relation to "normal controls." As David Rapaport(3) put it:

We can not be sure whether our own upbringing, which is hidden by privacy and restraining conditions, has or does not have the same kind and amount of "behavior problems" which become manifest in collective upbringing which lacks such hidden factors.

SAMPLE AND METHOD

This study was carried out in cooperation with the Education Department of Kibbutz Artzi.³ Its purpose was to explore the frequency and intensity of a wide range of behavior problems within the total population of children of three Kibbutzim. The settlements selected for this study may be considered as a cross section sample of the Kibbutz Artzi movement.⁴ The group investigated included all the children of these settlements up to the age of 12, totalling 403 children who have been followed on a systematic recording basis from the first few days of life.

The present report is limited to the analysis of the prevailing behavior problems in the sample of children investigated for a period of 12 months (throughout the year 1956). The data recorded include: 1. Developmental information gathered from the nurses' records; 2. Structured interview of the nurses and teachers on each child; 3. Interviews with the parents for additional information and tentative appraisal of the child-parent relationship; 4. Repeated psychiatric observation of the child in regular life situations, namely, interaction, with his group-mates, mealtime, child-parent meeting and bedtime.

An attempt was made to give precise definition to every one of the items under investigation in order to compare at each age level the extent of behavior deviation of the Kibbutz child in relation to a hypothetical "normal model." Although there was a theoretical recognition of the variability, lack of agreed standards, and difficulty of differentiating normal from abnormal behavior, the findings showed a reliable and positive correlation among the separate sources of information used in this research. A fair positive agreement to differentiate normal from abnormal behavior in a given child was found in the separate evaluations of the psychiatrist, nurse, teacher, and par-

ent. In the rather few cases of lack of agreement, a special coordination conference was held to deal with the reason of the different appraisals. The data were integrated by the author, who knew each one of the children and parents for a period of from 1 to 10 years—an average of 6 years.

A single 4 points scale for the scoring of behavioral items was used to include normal behavior, and slight, moderate, or marked deviations from the norm. The items selected for evaluation were mainly chosen with two goals in view: first, easy detection of the behavior item by direct observation performed by trained and untrained people involved in the research. Second, an attempt was made to pick out behavior characteristics which might uncover specific problems of the Kibbutz system of upbringing.

There were 217 boys and 186 girls; 219 were under the age of 6; 184 children 6 to 12 years old were attending primary school.

Table 1 shows the general findings in the total group of 403 children, while Table 2 presents the percentage of the prevalent behavior problems at different age levels.

From the data reported hitherto on behavior characteristics of large unselected groups of children (4, 5) it appears that the incidence of behavior problems among the Kibbutz children fits into the "normal range of deviation." The analysis of the data shows no evidence of unusual percentage of behavior problems attributable to lack of mothering, although some specific differences were found between Kibbutz children and family-raised children. It seems worthwhile to comment briefly on some of these findings and differences. A more detailed report on each item of behavior investigated will be published in separate papers.

RESULTS

Among the behavior characteristics and problems investigated, the highest peak of incidence was found in relation to thumb-sucking. The frequency of the symptom for the age-range of 1.6 to 12 was as high as 28% among 383 children surveyed. In most of the cases the thumbsucking was of mild or moderate intensity; in 5% the symptom was considered of marked severity. The frequency of this particular symptom increases at the age of 2, to reach its maxi-

³ I wish to express my deep gratitude to Shmuel Golan, Director of the Education Department, for his steady encouragement and helpful advice, as well as for providing the required facilities to implement this research. Limitations of space do not allow me to include the long list of nurses, teachers and educators of the children who cooperated so actively in this study.

⁴ Kibbutz Artzi constitutes one of the three largest federations of Kibbutzim in Israel.

TABLE 1
THE PREVALENCE OF SOME BEHAVIOR PROBLEMS IN A REPRESENTATIVE SAMPLE OF
403 KIBBUTZ CHILDREN UNDER THE AGE OF 12

Problems	Number of children surveyed	Age	Percentage of problem incidence	Percentage of marked deviation
Thumbsucking	383	1.6-12	28	5
Temper tantrums	383	1.6-12	12	1.5
Enuresis	283	3.6-12	11	—
Masturbation	350	1.6-11	9	.3
Aggression	383	1.6-12	8	2
Eating problems	403	0.1-12	7	.2
Nailbiting	383	1.6-12	7	0
Learning problems	184	6-12	7	0
Rhythmic Motor Habits	403	0.1-12	5	.5
Breath-holding Spells	199	1.6-6	3	.0
Night fears	383	1.6-12	2	1
Stuttering	343	2-12.6	2	0
Tics	306	3-12	1.6	0

TABLE 2
PERCENTAGE OF PROBLEM INCIDENCE AT SUCCESSIVE AGES
(SLIGHT TO MARKED DEGREE OF DEVIATION FROM NORMAL)
AGE IN YEARS—PERCENT OF PROBLEM INCIDENCE

Problem	Up to 2	2-3	3-4	4-5	5-6	6-7	7-9	9-11	11-12

Eating Problems	5	8	5	10	10	6	6	6	0
Nailbiting	0	0	0	2	10	18	13	12	6

num between the ages of 3 to 9, at a constant level. In this age-range 41% of the Kibbutz children were thumbsuckers. The figures given by McFarlane, *et al.*(4), as well as Lapouse and Monk(5) for corresponding samples of American children disclose a strikingly lower frequency of thumbsucking, ranging from two to 3 times less than the incidence reported for Kibbutz children. Among Kibbutz children thumbsucking declined rapidly only after the age of 9. No significant difference was found in the incidence of the symptom between boys and girls.

A comparative study was performed among 108 thumbsuckers age 1.6 to 11 and 225 Kibbutz children of the same age who did not present this symptom. No significant differences were found between the two groups as to the frequency and intensity of

additional behavior problems. In 26% of the thumbsuckers the symptom was a single one without further significant deviations in the behavior pattern. Where other behavior problems were present the comparison between the group of thumbsuckers and the control group did not reveal any differences of statistical significance.

It seems, therefore, that in a great percentage of Kibbutz children thumbsucking does not represent a consequence of emotional disturbance with increased dependency needs leading to regression to the security of the oral stage. The author assumes that there are at least two reasons to explain the remarkable incidence of thumbsucking in Kibbutz children. First of all, one has to take into account the brief nursing period. The weaning process is begun about the age of 3 months to be

carried on gradually for 6-8 months so that at the end of the first year of life the average baby in the Kibbutz is already weaned and starts feeding himself with a cup or a spoon. The short period of sucking experience may perhaps explain partly the increased incidence of the thumbsucking until a peak is reached at the age of 3. Actually, against this hypothesis stands the fact that there is not a higher frequency of thumbsucking at the age of 2 to 3 (24%) than that found in the United States among children who had a much more prolonged nursing period. McFarlane, *et al.* (4) found 27% of thumbsucking in children aged 1.9 to 3 years old. However, there is a striking difference from the ages 3 to 9, in which the thumbsucking persists and even increases, unlike control groups in which the frequency of the symptom decreases gradually. A possible explanation seems to be in the different approach to the child's symptom in the Kibbutz in relation to the usual family setting. On the whole, thumbsucking is seen by Kibbutz educators as a normal expression of oral gratification needs. Nurses, teachers and parents usually assume a permissive attitude toward the symptom, so that the children at any age may suck their fingers without any external interference. Thumb-sucking is simply ignored by the adults, who refrain from using any kind of device to stop it.

In sharp contrast to this high incidence of thumbsucking, a low incidence of eating problems was found in Kibbutz children. Out of 403 children, there were only 29 (7%) with feeding disturbances which included poor appetite and finickiness. Only in .2% of the children was the symptom severe. This figure is far below the usual frequency of eating problems in the family setting at every age level. Lapouse and Monk (5) found in a representative sample of 482 children aged 6 to 12, 20% with reported poor appetite, while at the same age level the symptom was present in only 4% of the Kibbutz children.

Other symptomatic manifestations in the oral area went along with the above findings and failed to reveal evidences of oral deprivation. The incidence of drooling and psychogenic vomiting was negligible. Nail-biting was extremely rare in Kibbutz chil-

dren under the age of 5, while among children from the age of 5 to 12, the frequency was 12%. This figure is about two to three times below the frequency found by McFarlane, *et al.* for children of the United States (4).

Speech problems were also infrequent among Kibbutz children. Out of 343 children between the ages of 2 to 12, seven children (2%), stuttered. Except for one child, whose stuttering was of a moderate degree, the rest of the group had a rather slight disturbance, and it could be assumed that it would disappear without any special treatment.

Autoerotic manifestations like masturbation and rhythmic motor habits (head rolling, self-rocking, *etc.*) did appear apparently in a similar frequency to the usual estimate for an unselective sample of children. In the Kibbutz setting these are symptoms that may be easily detected. The same rule of non-interference on the part of the educator that was pointed out in the case of the thumbsucking, applies to masturbatory activities. The educator shows a permissive non-punitive attitude and the child masturbatory activity is ignored. For the purpose of this research all play or self-occupation with the sexual organ which was repeated deliberately as a pleasure seeking device was noted as masturbation. The total incidence of masturbation among 383 children at the age-range of 1.6 to 11 was 9%. This figure is somewhat higher than that found by McFarlane (4) for 116 children of the same age (about 5%). It may be assumed that the difference is partly due to difficulties to get accurate data on this matter from the private family. However, it is also possible that the difference is partly related to the parental restraining attitude and disapproval in the private family leading to repression of the autoerotic activity.

Comparison between 122 children at the oedipal age (3 to 6 years old) and 151 older children in the so-called latency period (6 to 11 years old) did not disclose any significant difference in the frequency of masturbation. Both groups showed a similar figure: 10% of masturbation for the "oedipal group" and 11% for the group in the "latency period." As to sex, a significant

prevalence of masturbation among boys was observed in relation to girls, the ratio being $2\frac{1}{2}$ to 1.

The problem of enuresis and encopresis was thoroughly investigated in 283 children between the ages of 3.6 to 12, and it will be dealt in detail in a separate paper. The incidence of enuresis among 283 children was 11% comparable to a representative sample of "normal" children. Yet, comparative evaluation is difficult to establish either because most of the figures on enuresis refer to selected samples of deviant children, or because the figures reported lack accuracy. In most of the papers published hitherto, the prevalence of enuresis has been determined by data collected during occasional home visits in absence of a close followup.

A definite difference in distribution of enuresis by sex was noticed: 73% who wetted were boys and only 27% were girls.

Every enuretic child was studied separately in relation to the presence of other behavior disorders, antecedents of enuresis among siblings and parents, characteristics of child-parent relationship and possible clustering of different types of enuretic children. These findings will be reported elsewhere.

Encopresis was a rare finding among 283 Kibbutz children between the ages of 3.6 to 12. Only two children (.7%) presented soiling of mild intensity, one of them accompanied by enuresis.

Another symptom studied was the presence of repeated night fears. It came as a surprise to us that only two children (1%) presented night fears. Nine additional children were reported as having shown this disturbance in the past two years, an incidence of 3% in 383 Kibbutz children aged 1.6 to 12. This incidence seems to be rather low in comparison with usual figures on night fears frequency. This is particularly striking since the children are alone for most of the night, far away from their parents' houses, while one night watch goes from house to house to check on all the children. Since each round of the night watch requires approximately one hour, maybe additional instances of mild night fears could not be detected and reported.

Several observers have reported a rather

high incidence of excessive aggression among Kibbutz children in the toddler and nursery age. Caplan's (2) impression was that Kibbutz preschool children . . . "show an uncontrolled aggression which exceeds by far that which is found among children in normal family circumstances." No objective data were given to confirm this assumption. Moreover, again we do not have reliable comparative data obtained in other types of upbringing.

A careful observation of a group of 383 children ranging in age from 1.6 to 12 was made with regard to the presence of acts of aggression in which a child appears to be repeatedly motivated to hurt or harm another. Acts of aggression were considered those instances in which force was used to take objects or toys from other children, or the play of other children was disturbed by pushing, hitting, biting, destructiveness, etc. Children who showed cruelty to animals or people were also included in this category.

It appears that 33 out of 383 children observed (8%) showed different degrees of repeated aggressive behavior. In the great majority of these aggressive children the extent of deviation was considered slight or moderate. Only in 6 children (1.5%) was the deviational aggressive behavior qualified as severe.

As has been reported by other observers, a noticeable sex difference was noted with regard to aggression. Aggressive behavior was 4 times more frequent among boys than among girls (27 to 6).

Likewise, there were differences in the incidence of aggression according to the age-range. Out of the 199 children in the preschool age, 21 children (10%) were classified as aggressive. On the other hand, among 184 children between the ages of 6 to 12 there were only 12 (6%) aggressive ones. This difference probably applies to any kind of upbringing and reflects the effect of socialization in the gradual formation of inner controls. Apparently, the above figures on aggression among Kibbutz children do not substantiate the impression of an unusual, excessive frequency for this symptom. Hyper-aggression in 32 out of 33 children occurred in relation to several other problems which appear with sig-

nificant higher frequency in these children in comparison to the total group. Aggression, temper tantrums, fears, enuresis and nailbiting constituted a definite interrelated cluster of symptoms. While temper tantrums appeared 4 times more frequently among aggressive children than in the total group, fears, enuresis and nailbiting were present two to three times more often in the hyper-aggressive sample of children.

As regards the frequency of temper tantrums, once again we should face the difficulties of establishing the delimitation between normal and abnormal reaction. The symptom was considered and quantified when the child's rage outbursts exceeded in intensity and frequency those of a theoretical "normal model" for the specific age. Each child who reacted with temper tantrum in a repetitive way in response to frustration (at least once-a-day as an average) or had less frequent but unusually intense outbursts, was classified in a separate group. Using this criterion 49 (12%) out of 383 Kibbutz children were included in the group of children with deviant temper tantrums. In 5 children (1.3%) the temper tantrum was severe enough to be considered a major symptom. Temper tantrums declined from the age of 7 onward. Among 232 children under 7, repetitive temper tantrums were found in 40 (17%). On the other hand, the symptom was present in only 9 (6%) out of 151 children in the age range of 7 to 12. Lapouse and Monk(5) who tried to quantify the intensity and frequency of temper tantrum in a representative sample of 482 children aged 6 to 12 found a percentage of 11% in which the outbursts appeared once a day or more. Among 184 Kibbutz children of the same age the percentage of temper tantrum of similar frequency was 9%.

A striking similar percentage of temper tantrums incidence was obtained among boys and girls in the group of 49 Kibbutz children with this symptom.

Breath-holding spells as a result of anger or frustration were reported in a very low percentage of the children. They were observed in 6 children from the ages 1.6 to 3, an incidence of 2.7% among the preschool children.

SUMMARY

The Kibbutz has produced a method of upbringing planned to fit its interests, needs and goals. The most significant differences between the Kibbutz system of education and the traditional Western family can be set down under three headings: the transfer of several parental functions to other adult figures; the importance of the peer group for the Kibbutz children; and the similarity of roles assumed by father and mother in the child-parent relationship.

The child is raised in a rather stable peer group whose importance for the child steadily increases from the second year of life on. The process of socialization is mainly achieved through this very early and constant group interaction, with the nurse assuming the role of socializer.

The father in the Kibbutz usually spends more time with his children than in the traditional Western family. Beginning with the second year of life the father is with his children for the same period of time as the mother using this time in most of the cases to be a playmate. The usual sex distinction between the role of provider and caretaker does not exist in the Kibbutz. Despite these striking qualitative differences in their upbringing, the Kibbutz children seem to fit into the normal range of behavior pattern.

A study was designed to explore the frequency and intensity of a wide range of behavior problems within the total population of 403 children aged 1 to 12 years in three different Kibbutzim. No evidence was found of unusual percentage of behavior problems attributable to emotional deprivation. With regard to frequency and intensity of most of the symptoms the findings seem either to match the usual figures in "normal controls" or even appeared less prominently. This was observed in relation to symptoms like aggression, temper tantrum, breath-holding attacks, enuresis, rhythmic motor habits, speech problems, nailbiting, and night fears. A very peculiar difference is the inverted ratio between thumbsucking and eating problems. Kibbutz children at different age levels had 3 times more thumbsucking and about 3 times less eating problems than "normal control groups." No significant differences were found with re-

gard to additional behavior problems between 108 thumbsuckers and 225 Kibbutz children who did not present the symptom. The apparent explanation for the high incidence of thumbsucking, in addition to the early weaning of the Kibbutz infants, seems to be the very permissive approach to the symptom. The low frequency of eating problems and psychogenic vomiting reflects most likely the fact that the feeding functions and training is in charge of the nurse instead of the mother from the end of the first year of life.

In the Kibbutz, as in the traditional family, the parents constitute the most important figure in the child's life. Deviant behavior of Kibbutz children—with exclusion of constitutional factors—is due in the great majority of cases to a disturbed child-parent relationship.

Rich opportunities for research in normal child development are provided by the Kib-

butz system of education, and as Bowlby (1) has stressed . . . "it is to be hoped these will not be missed."

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

AMITRIPTYLINE (ELAVIL), A NEW ANTIDEPRESSANT

JOSEPH A. BARSA, M.D., AND JOHN C. SAUNDERS, M.D.¹

To date, the most effective antidepressants have been the monamine oxidase inhibitors and imipramine. These drugs, however, have limitations in the treatment of depression in schizophrenic patients, for they will frequently exacerbate the symptoms of schizophrenia, causing the delusions and hallucinations either to appear for the first time or to become more florid. This untoward effect is more marked with the monamine oxidase inhibitors than with imipramine.

The purpose of the present study was to test the effectiveness of a new antidepressant, amitriptyline hydrochloride (Elavil),² in the treatment of chronic psychotic patients manifesting depression in addition to their other symptoms. Amitriptyline is not a monamine oxidase inhibitor, but is related chemically and pharmacologically to imipramine.

Twenty-eight female patients between the ages of 31 and 60 were chosen for the study. They had been continuously hospitalized from 1 to 23 years. Their diagnoses were as follows: 19 schizophrenia, 4 involutional psychosis, mixed type, 2 manic-depressive psychosis, mixed type, 1 psychosis with epidemic encephalitis, 1 psychosis due to alcohol, deterioration, 1 psychosis due to epilepsy, deterioration.

The description of the patients varied, but on the whole they were clean and neat in appearance, passively cooperative, seclusive, withdrawn, depressed rather than flat in affect, delusional and hallucinated. In 15 patients the depression was agitated, and in 13 quiet and retarded.

All had been on tranquilizing drugs for

at least a year, with slight or no improvement in their symptoms. Nineteen had also received a 1 to 3 month course of imipramine in conjunction with the tranquilizing drugs. Of the latter group, 8 patients showed slight improvement in depression with imipramine, 5 no improvement, and 6 grew worse on imipramine, becoming more tense, restless, agitated, and responding more to their delusions and hallucinations. Imipramine was discontinued prior to the present study.

At the start of the study, all of the patients were receiving various tranquilizing drugs. Five were receiving chlorpromazine, 6 a combination of chlorpromazine and trifluoperazine, 5 thioridazine, 8 levomepromazine, 1 prochlorperazine, 1 a combination of prochlorperazine and promazine, and 2 fluphenazine. The dose of the tranquilizers remained unchanged, and amitriptyline was added to the medication, starting at 25 mgs. t.i.d. and gradually increasing in dose until favorable results were obtained. The highest dose used was 50 mgs. q.i.d.

Amitriptyline was continued for 3 to 5 months. At the end of this period, 3 patients were completely free of depression, 17 showed considerable improvement in their depression, 5 slight improvement, and 3 no improvement. Of the 19 patients who had previously received imipramine, 16 were more improved on amitriptyline, and none gave evidence of aggravation of psychotic symptoms on the latter drug. Three patients responded to imipramine and amitriptyline in an equal manner, one with slight improvement and two with no improvement. As with imipramine, the antidepressant effect of amitriptyline was gradual, significant relief of depression appearing usually within 2-4 weeks.

¹ Rockland State Hospital, Orangeburg, N. Y.

² This drug was supplied by Merck Sharp & Dohme Laboratories, West Point, Pa.

Side-effects with amitriptyline were few. Two patients felt weak and dizzy in the first three days of therapy, but this symptom then disappeared. One became too stimulated and euphoric on 25 mgs. t.i.d., and this was controlled by reducing the dose to 25 mgs. b.i.d. Blood and urine examinations revealed no abnormalities during the course of the study.

In summary, amitriptyline hydrochloride

(Elavil) is an effective antidepressant. It resembles imipramine hydrochloride both chemically and in its clinical action, but it appears to have the advantage of more potent antidepressant effect and less proneness to exacerbate the symptoms of schizophrenia. Therefore, it is especially useful as an adjunct drug in the treatment of schizophrenics who manifest depression in addition to their other symptoms.

CHLORZOXAZONE AS AN ADJUNCT TO ELECTRIC CONVULSIVE THERAPY

OTTO L. BENDHEIM, M.D.¹

Chlorzoxazone² was studied in an effort to find a simple and effective oral relaxant to minimize the hazard of fractures resulting from seizures produced by electric convulsive therapy.

Chlorzoxazone, an orally effective skeletal muscle relaxant was used as premedication in 55 patients with depressive disorders who received from 2 to 18 electric convulsive treatments, so that a total of 464 were given throughout a one-year study period.

The dosage of chlorzoxazone was 1000 mgm. the night before and 500 to 1500

mgm. about two hours before the ECT, which was administered in the morning. The second dose varied with the weight of the patient and the intensity of the seizure anticipated.

Slight giddiness and muscular weakness in two older patients, requiring extra post-treatment bedrest, were the only side effects noted.

Patients receiving chlorzoxazone before electric convulsive therapy were found to be less tense and apprehensive and easier to handle. Premedication with chlorzoxazone resulted in a marked reduction of muscular pull during the electrically induced seizure, with concomitant sharp decrease in incidence of fractures.

¹ Medical Director, Phoenix Institute of Neurology and Psychiatry, Camelback Hospital, Phoenix, Arizona.

² The chlorzoxazone used in this study was supplied as Paraflex® by McNeil Laboratories, Philadelphia, Pa.

EVALUATION OF PLEXONAL AS A TRANQUILIZER IN THE GERIATRIC CARDIAC PATIENT

H. DAVANLOO, M.D.¹

Of all institutionalized patients, it seems fair to say that those in the older age brackets, the geriatric population, present the greatest therapeutic challenge. While the phenothiazines constitute a milestone in the treatment of emotional disorders, they have been less than satisfactory in controlling anxiety and agitation in the geriatric patient because of their propensity to in-

duce extrapyramidal stimulation and hypotension at dose levels below those which provide adequate tranquilization. Various sedatives have also been employed and found wanting because they are apt to induce confusion, disorientation and stupor in the aged patient.

Control of anxiety and tension has been an especially difficult problem in patients with cardiovascular disease. Accordingly, it

¹ Box 349, Waltham, Mass.

was with a good deal of interest that we noted the results reported by Scheifley² with the preparation, Plexonal.³ In a study conducted at the Mayo Clinic, he found this agent markedly effective in relieving anxiety, tension, and restlessness in hospitalized cardiac patients. We were particularly impressed by the decided superiority of Plexonal over meprobamate. It occurred to us that the results we had obtained with the latter, which we had used extensively in our patients, could serve as a yardstick by which we could measure the efficacy of Plexonal.

Plexonal² was tested in 40 patients in a female ward of Metropolitan State Hospital. Their ages ranged from 50-85 years and all demonstrated anxiety and restlessness associated with heightened heart consciousness and preoccupation with their blood pressures. At the time this study was initiated, 26 of these patients were receiving meprobamate for their anxiety and 21 were receiving sodium pentobarbital for insomnia. These drugs were withdrawn several days before instituting Plexonal. No change was made in the regimen of cardiotonic or hypotensive agents employed in the 15 cardiac patients and 10 hypertensives.

The dose of Plexonal ranged from 2 to 5

³ Sandoz Pharmaceuticals. Contains: sodium phenobarbital 15 mg., sodium barbital 45 mg., Sodium sandoptal 25 mg., scopolamine HBr. 0.08 mg., Dihydroergotamine 0.16 mg.

tablets daily. Within 5 days, there was an appreciable reduction in restlessness and anxiety in 33 patients along with a noticeable improvement in mood. The most gratifying results were achieved in those with insomnia, which was relieved in 19 patients by a dose of one Plexonal tablet after each meal and two at bedtime. Depression in two patients was made worse and did not respond until imipramine was added to the daily dose of Plexonal. This combination was maintained for two weeks, after which the dose of Plexonal was gradually reduced until it was removed completely. No appreciable effect was observed in 3 patients, 2 of whom were classified as severe hypochondriac states, while another 2 patients reacted with excessive drowsiness.

A comparison of Plexonal with the therapy previously employed showed that 17 did better on Plexonal than on meprobamate, 6 did better on meprobamate than on Plexonal and 3 responded the same to both. Of the 21 who had received sodium pentobarbital earlier for insomnia, 16 demonstrated improved sleep patterns after switching to Plexonal.

SUMMARY

This study indicates that the integrated activity of the ingredients in Plexonal makes it an effective and well-tolerated preparation for the relief of anxiety and restlessness in the geriatric patient. A significant finding was the relief of insomnia which carried over from the daytime use of Plexonal.

CONTROL OF HYPERCHOLESTEREMIA AND HYPERLIPEMIA IN A NEUROPSYCHIATRIC HOSPITAL

J. R. SHAWVER, M.D., J. S. SCARBOROUGH, M.D., AND
S. M. TARNOWSKI, M.S.¹

A review of the literature indicates that the concept of association of atherosclerosis with levels of cholesterol and lipids is tentatively accepted. We were interested in the practicability of attempting to control this disorder of lipid metabolism in patients who are also subjected to intensive psychiatric therapy. Treatment was with massive

quantities of nicotinic acid as recently reported.²

Patients in this initial study have a common diagnosis of schizophrenic reaction, chronic undifferentiated type, one G.T.G. having had a leukotomy in 1954. Their ages vary from 26 to 42 and all are on different

tranquilization drugs, promazine, chlorpromazine and reserpine. The period of hospitalization is from 4 to 9 years and adjustment is satisfactory only to the degree that each is on partial privilege. After an indicated control period, 3.0 Gms. of nicotinic acid was administered in the form of 750 mg. per capsule, q.i.d., while on a standard hospital diet throughout the study. The results at the end of 30 and 60 day intervals are seen in Table 1.

The reduction of hypercholesteremia and hyperlipemia was remarkable as reflected by values of total cholesterol, total lipids, phospholipids, and lipoproteins, the latter

being partitioned into beta and alpha fractions. No side reactions were noted in this small series of patients. After attaining optimal levels, nicotinic acid was reduced to 1.5 Gms. per day for an additional period of 30 days. This amount of drug failed to maintain previous levels, particularly in two of the individuals.

CONCLUSION

Control of hypercholesteremia and hyperlipemia in a neuropsychiatric hospital apparently is practical during treatment of psychotic patients employing massive amounts of nicotinic acid.

A CLINICAL TRIAL STUDY OF IMIPRAMINE HYDROCHLORIDE¹

NINA KATERYNIUK, M.D., AND CHARLES W. MORRIS, M.D.²

The present study involved 34 subjects: 18 women and 16 men, treated with the drug for 20 to 130 days (average 58 days). Diagnostic classifications are shown in Table 1.

Ages varied from 20 to 75 years, 31 of these patients had previous hospitalizations.

¹ Geigy Pharmaceuticals, Saw Mill River Road, Ardsley, New York, generously provided the imipramine hydrochloride used in this investigation.

² Respectively, Chief of Medical Staff and Clinical Director, Central State Hospital, Lakeland, Ky.

All showed need for treatment. Manifestations of depression differed according to the basic pathology involved, though several common features characterized the total group. Nine patients were severely depressed and suicidal. Subjects' response to previous treatments had been unsatisfactory.

Before the imipramine hydrochloride trial, all medicines other than those given for physical disorders were discontinued.

Three patients continued or started on electric shock treatment.

The average initial dose of imipramine hydrochloride, given orally, ranged from 50 to 75 mgs. per day, not exceeding 200 mgs. Duration of treatment was 20 to 130 days, with three-fourths of the patients receiving the drug for a period of 2 months.

All patients were examined immediately before, during and at the end of the observation period. The patient's physician and the nursing staff reported each subject's progress. Behavior, mood, verbal content, sleep patterns and appetite received close attention, the patients being encouraged to discuss their complaints and their emotional status.

Diminution or disappearance of pathological features, especially depression is designated as "improved." Lack of changes in symptoms is described as "unimproved"; and increase or aggravation is classified as "worse."

Twenty-seven (79%) patients improved; seven (21%) remained unimproved; and none became worse (Table 1).

TABLE 1

Diagnosis	Improved	Unimproved
Psychotic depression	7	2
Neurotic depression	5	0
Involuntional depression	1	1
Mental deficiency with psychosis	1	0
Organic brain syndrome	3	1
Paranoid reaction	1	0
Schizophrenic	9	3
Total	27	7

DISCUSSION

It is noteworthy that 3 manic-depressive depressed showed marked improvement after 4 to 6 weeks of treatment. Six patients improved when the drug was given in a combination with EST; 4 others, however, had not improved on EST several weeks before imipramine hydrochloride treatment. Six patients received the drug combined with tranquilizers to ameliorate mild excitement or sleep disturbance.

No allergic manifestations and no side effects other than transient episodes of dizziness, reported by 2 elderly patients, were observed. Temperature, pulse, respiration and blood pressure showed no aberration.

According to the available records, the improvement with imipramine hydrochloride observed in *schizophrenics* is *less well sustained and fluctuating*. In the majority of improved schizophrenics, imipramine hydrochloride given alone or in combination with tranquilizers replaced to an extent the indication for electric shock treatment. This refers to the schizophrenic "pseudo-depressive" states such as despondency, guilt, suicidal preoccupations, reduced spontaneity, withdrawal, etc. In general, schizophrenic subjects showed symptomatic improvement only.

All the patients who failed to improve had earlier failed to improve on conventional treatment methods.

In summary, 27 of 34 patients treated with imipramine hydrochloride showed distinct improvement. "Pure" depression (neurotic or psychotic) abated more readily than depressive symptoms in schizophrenia and brain syndrome.

METHAMINODIAZEPOXIDE (LIBRIUM) IN CHRONIC REFRACTORY ANXIETY

ALFRED H. VOGT, M.D.¹

In February of 1960, a quantity of methaminodiazepoxide was obtained from Roche Laboratories for the purpose of determining its effect in cases of chronic refractory anxiety. A group of 17 patients (12 women

and 5 men) was selected for the study, primarily, on the basis of being chronically "anxious" despite all previous treatment. The average stay in the hospital of these patients was about 2½ years. The average over-all length of illness was 33 months.

¹ Central Louisiana State Hospital, Pineville, La.

Previous treatment ranged from extensive individual psychotherapy, electroshock, and insulin shock to the use of one or more of the tranquilizers in all patients. Diagnostically they were categorized as follows:

Psychoneurosis, Anxiety Reaction	2
Psychoneurosis, Conversion Reaction	2
Psychoneurosis, Obsessive Compulsive Reaction	1
Childhood Schizophrenia	1
Schizophrenic Reaction, Chronic Undifferentiated type	5
Schizophrenic Reaction, Paranoid type	4
Unclassified Psychotic Reaction	1
Manic-Depressive Reaction, Depressed type	1

METHOD

Before treatment all patients were screened. This consisted of termination of previous medication, an evaluation of the physical and mental status, and the assessment of the patient's statements about his or her anxiety. Attendants, nurses, and physicians were asked to render their observations regarding each patient. Dosage schedules were defined so that each patient would receive 25 mgm. of methaminodiazepoxide 4 times a day for one month.

RESULTS

Improvement depended on clear cut observation by the staff that the patient was markedly, moderately, or slightly improved. Marked improvement refers to sustained relief of symptoms of restlessness, complaints of tension, excessive perspiration, inability to concentrate, and preoccupation. The markedly improved patient tended to participate in ward activities and to socialize more with other patients. Moderate improvement refers to the condition where the preceding features were less obvious and less sustained. Slight improvement refers to a selective relief from certain symptoms and little or no change in the patients' observed behavior. The categories of "unchanged" and "made worse" explain themselves. During the study period no patients received ECT. Two patients with severe thinking disorders required thifluoperazine or chlorpromazine to control disturbed behavior. One patient required meprobramate to go to sleep at night. The over-all results at the end of one month were as follows:

Marked Improvement	6
Moderate Improvement	7
Slight Improvement	1
Unchanged	1
Made Worse	2

Those patients who were "made worse" evidenced extremely aggravated behavior and severe thinking disorder after the first week of therapy; one complained to the nursing staff that the drug "seemed" to increase the symptoms of anxiety. Associated with this was the report that one patient had developed very active sexual preoccupations.

SIDE EFFECTS

Side effects encountered with methaminodiazepoxide were quite common when dosage schedules exceeded 100 mgm., at which time dosage was reduced. The usual reduction was to 50 mgm. per day. Very often side effects were seen when the dosage was again brought up to the 100 mgm. level after being previously reduced.

The following illustrates the nature and frequency of side effects of methaminodiazepoxide when the dosage is held at 100 mgm. per day:

Ataxia	3
Drowsiness	4
Palpitations	2
Intense erotic feelings	1
Dyspepsia	1
Slurring speech	1
Increased appetite	14
Deeper sleep with tendency to fall asleep while sitting in a chair or resting	6

One severely anxious schizophrenic female patient evidenced all of the side effects and was discontinued from the study after the second week. Reduction of the dosage to 50 mgm. per day alleviated the side effects but did not improve the anxiety or the psychosis. One male patient who was making a good adjustment to the drug initially became panicked after an argument with another patient. He was progressively more preoccupied with "killing" this person. He felt that he could not control himself and felt that the drug possibly contributed to his feeling so helpless in the face of his impulses. The drug was withheld, and the preoccupation rapidly disappeared.

CONCLUSION

Methaminodiazepoxide appears to be quite effective in a wide range of mental disorders where severe anxiety is present. In each instance where there was marked or moderate improvement in the study group, the patient became more sociable,

conversant, and noticeably less fearful and preoccupied.

I am grateful to the Roche Laboratories for supplying the drug used in this study, and to the staff of Warren State Hospital for their participation in this effort.

TREATMENT OF SCHIZOPHRENIA WITH PROKETAZINE

JANE E. OLTMAN, M.D., AND SAMUEL FRIEDMAN, M.D.¹

Proketazine,² a new phenothiazine compound, is similar in structure to perphenazine, the chlorine radical in perphenazine being replaced by a propanyl radical in proketazine. We have been using proketazine and its earlier analogue for approximately a year. The material for this study consisted entirely of female schizophrenic patients. Initially, a small group of 16 chronically ill patients was treated. These individuals had been ill for many years; their hospitalization ranged in duration from 3 to 31 years, with a median of 19 years. They had been previously, and unsuccessfully, treated with the usual gamut of somatic therapies and a variety of ataractic drugs. Initial dosage for this group was 100 mg. daily. This was increased progressively, by weekly increments of 50 mg., to 450 mg. daily, with a total treatment period of 8 weeks. Results in this group of hard-core schizophrenics were essentially negative. Some degree of mild behavioristic effect was noted in a few individuals, but significant improvement was lacking.

The major portion of the study was devoted to patients newly received on the female admission service. They represented a typical cross-section of schizophrenia. They ranged in age from 14 to 62; however, almost two-thirds were in the 3rd and 4th decades of life. The total duration of illness varied considerably—from a few days to 30 years. The duration of present illness was as follows: under 1 year—48%; 1 to 2 years—21%; over 2 years—31%. Dosage ranged chiefly from 50 to 150 mg. daily, and the

treatment period from 4 to 16 weeks. Of this group of 87 patients, 36 (41%) were much improved or in remission; 25 (29%) were improved, and 26 (30%) were essentially unimproved. For comparison, a smaller series of 18 patients treated by placebo therapy during the same period exhibited the following results: much improved, 11%; improved, 22%; and unimproved, 67%. The results with proketazine were generally similar to those obtained with perphenazine in a group of 44 patients treated during the same period.

More detailed analysis of the factors which contributed to successful results indicated that the latter were associated with features which have long been recognized as favorable prognostic criteria in dementia praecox. These are in the area of duration of present illness, type of onset and reaction of the patient, and type of symptomatology. Thus in approximately 80% of drug-treated patients who exhibited an A level of improvement (much improved or in remission) the present illness was less than 1 year in duration, whereas the illness was more than 2 years in duration in 65% of those with unsuccessful result. An A level of improvement was obtained in 72% of patients whose illness was characterized by relatively acute onset and whose reaction might be termed a vigorous one. On the other hand, only 21% of patients with an insidious type of onset, and a passive, constricted, non-vigorous type of reaction attained this level of improvement. With respect to type of symptomatology, some 75% of patients who experienced active delusions or hallucinations, acute feelings of unreality, ideas of reference and projection phenom-

¹ Fairfield State Hospital, Newtown, Conn.

² Generous supplies of Proketazine were furnished by Wyeth Laboratories, Philadelphia, Pa.

ena, especially if these were associated with a sense of impending danger or catastrophe, responded with maximal degree of improvement. On the other hand, patients whose thought processes were poorly organized, and characterized by rather diffuse fantasies, feelings of inadequacy or inferiority, vague gropings toward an ill-defined goal and expressions of all-pervading interpersonal difficulties, exhibited generally unrewarding results. In many instances, prokazine appeared to exhibit an almost specific anti-delusional and hallucinatory effect in the acutely ill patient.

Significant complications were absent. Liver function profiles and transaminase levels remained within normal limits. Side-

effects consisted chiefly of extrapyramidal features. Parkinsonism appeared in 11 patients, akathisia in 8, and both features in 6, for a total of 29%. As a rule, the Parkinsonism was relatively mild and it was readily controlled by appropriate drugs. Subjectively, akathisia was somewhat more troublesome. One patient exhibited oculogyric crises as part of the Parkinsonism syndrome. Somnolence was relatively mild; it usually disappeared with time.

In conclusion, therefore, it may be stated that prokazine is a satisfactory antipsychotic agent and that it is therapeutically effective in appropriate cases of schizophrenia.

THE VARIATION IN CLINICAL RESPONSE TO MARPLAN¹ WITH DURATION OF ILLNESS

ROBERT R. SCHOPBACH, M.D.²

This paper indicates that the effects of hydrazines upon depressions vary with the duration of the illness. A lowered serotonin metabolism in depression is also suggested. The 28 subjects were divided approximately equally between the sexes and between inpatients and outpatients. Each inpatient had a private room in a 24-bed open psychiatric floor of a 1,112-bed general hospital. Six full time psychiatrists and three residents gave close personal supervision and intensive therapy to these patients. All were treated by the author aided by the residents. There is a special occupational therapy unit on the floor and psychologic and social service assistance is constantly available. The average hospital stay is about three weeks. The sight of others recovering and going home enhances the favorable atmosphere for recovery. Thus improvement can never be attributed entirely to any medication and these factors may explain the almost immediate improvement of 3 of this group.

Routinely 30 mg. Marplan per day was

given either in one dose or divided to spread the psychologic effect of taking "that new medicine for depression that was described in the magazines." Usually this dose level was continued for 3 weeks, then gradually decreased and, after approximately two months, discontinued. In 2 cases in which the medication was discontinued prematurely or abruptly, the depression reappeared but was again dispelled by the medication.

Of the 28 patients only 6 were suffering from an acute depression, in the others the symptoms had been present for at least a few months and usually were associated with a chronic anxiety state or a long history of other neurotic difficulties. Of these 6 acute depressions 2 cleared within 1-2 days, making it doubtful that the drug was the responsible curative agent. Such responses are recorded as indeterminate. Three of the remaining 4 obtained relief within 3 weeks from Marplan alone. The fourth man demanded that everything possible be done as rapidly as possible; he was therefore given ECT in addition shortly after starting to take Marplan. He improved so markedly after only 2 ECT that he was discharged to continue taking the drug at home where he

¹ Marplan, a benzyl hydrazine, and a grant were generously furnished by Hoffman La Roche Company.

² Psychiatric Division, Henry Ford Hospital, Detroit 2, Mich.

continued to improve. This was a definite decrease in the number of ECT required to produce such a response when compared with similar patients not taking hydrazines.

The results in the group of 22 more chronically disturbed depressed patients were less gratifying. Eight did report complete relief and 2 of these even became slightly euphoric but this condition subsided when the dose was reduced. Three continued to have the same general neurotic complaints but were somewhat less despressed. Eight were unaffected by the drug. One of these later improved with imipramine and another with ECT while 6 remained depressed although still ambulatory. Three were classed as indeterminate; one lost all symptoms almost immediately after admission; the other 2 had considerable concomitant ECT and psychotherapy so that their improvement could not be attributed to any one factor. Thus, as with all therapies, Marplan is more effective in acute depressions but is still of definite value in those of longer duration. It may also serve to decrease the number of ECT needed.

It had been planned to obtain white blood counts and transaminase tests for liver function before and during drug therapy, but these were obtained in only 19 and 15 patients respectively. No significant alterations were found. The highest and lowest white blood counts during therapy were 9900 and 5350. The normal serum transaminase values are anything less than 30.³ Pretreatment values ran as high as 24 but during treatment the highest was only 14. There was a definite tendency for these values to decrease slightly during therapy. This may reflect a general improvement in dietary intake and physical well being. There was no clinical evidence of liver disorder among this group. There were some complaints of dryness of the mouth and of dizziness but only slight hypotension was observed and in no case was it necessary to decrease the medication because of these minor side effects.

³ Reitman, S., and Frankel, S.: *Am. J. Clin. Path.*, 28: 56, 1957.

INTERFERENCE OF INDICAN IN THE ESTIMATION OF PHENOTHIAZINE

JEROME LEVINE, M.D., DONALD LEVINE, B.A.,¹ AND
S. MOUCHLY SMALL, M.D.²

Recently several articles concerning the detection of phenothiazine derivatives and their metabolites in the urine have been published(1-7). These tests were designed to offer a simple and immediate check of whether a prescribed dosage of phenothiazine had actually been ingested by a psychiatric patient either in a hospital setting or in private practice.

These tests were performed in our laboratory and a high percentage of false positives was found with many of the tests. Heyman (7) reports approximately 15% false positives with both the Forrest Universal and Forrest Piperazine-linked Phenothiazine

Tests. In addition a poor correlation was found in most instances between the amount of phenothiazine ingested and the color produced.

One major cause of the false positives and poor quantitative results was found. The reagents in the Forrest Vesprin Test(3), the Forrest Piperazine-linked Phenothiazine Test(4), the Forrest Universal Test(5), and the Forrest Thioridazine Test(6) cause a blue color production in the presence of indican. Indican is a degradation product of tryptophan; it is a normal constituent of urine and the amount present is a function of diet, peristaltic activity, intestinal putrefaction and other factors. No color due to the presence of indican was caused by the reagents in the Forrest Chlorpromazine, Promazine and Pacatal Test(1, 2).

¹ Supported in part by National Institute of Mental Health, Summer Fellowship Grant 2M-6004-C4.

² From Department of Psychiatry, Edward J. Meyer Memorial Hospital, Buffalo, N. Y.

If the urine contains a significant amount of indican (as shown by the Obermayer Test) and is tested for the presence of phenothiazine, a false positive or an increased amount of color may result.

The fact that the color produced is due to indican was proved in the following man-

Spectral absorption of chloroform layer obtained from (a) Obermayer Test (for indican) (b) Forrest Test(4).

ner: Control urines (from persons not receiving phenothiazines) were examined with the tests proposed by Forrest(3-6). Those which gave a color were immediately extracted with chloroform and a sky-blue color appeared in the chloroform layer. The chloroform layer was then analyzed spectrophotometrically. The Obermayer Test was performed on a sample of the same urine and the resulting chloroform layer was also analyzed spectrophotometrically. The absorption spectra obtained with a Cary Model 11 Recording Spectrophotometer⁸ appear below. Since the curves are so similar it is concluded that the color produced by the phenothiazine tests are due to the presence of indican. In addition, the curves are in agreement with that proposed by Rimington(8) for indican.

The color production due to indican can be prevented by the addition of a drop of formaldehyde to the urine. Unfortunately, when testing for phenothiazines, the formaldehyde reacts in some way with the urine and test reagents to form an interfering pink color.

A test which eliminates the production of color due to indican is currently being devised. We recommend that the commonly used phenothiazine tests(3-6) be re-evaluated in view of this finding.

CLINICAL EXPERIENCE WITH A NEW PHENOTHIAZINE (PIPERACETAZINE)¹

K. HAWORTH, M.D., L. M. JONES, M.D., AND W. MANDEL, M.D.²

Piperacetazine is a new phenothiazine derivative of the piperidine series (2-Acetyl-10-[3-[4-(B-hydroxyethyl) piperidino]propyl]-phenothiazine) with the following structural formula :

Clinical experience with this drug was gained in observing its effects in 75 recently admitted psychiatric patients, 43 men and 32 women, considered suitable for treatment with phenothiazine medication. The diagnoses were: schizophrenic reactions, 56 (paranoid, 18; catatonic, 12; schizoaffective, 8; undifferentiated, 18), affective reactions, 14, and nonpsychotic reactions, 5. The patients' ages varied between 16 and 67 years, the mean being 32 years. Observations were made only during the patients' stay on an acute treatment ward. Global ratings of marked, moderate, slight, or no improvement in terms of mental status and behavior were made in each patient at the termination of his treatment. A C.B.C., urinalysis, serum bilirubin and serum glutamic pyruvic transaminase were performed prior to the start of drug, at the second and fourth weeks and each month thereafter as long as the patient was receiving piperacetazine. When elevated serum transaminase values occurred, weekly determinations were performed until the values returned to the normal range.

Treatment was started in oral dosages of 5 to 10 mg. b.i.d. or t.i.d. and was progressively increased until improvement or

side reactions occurred. The duration of treatment varied from 6 to 165 days, the mean being 67 days for the men, 41 days for the women and 54 days for both sexes. The daily maintenance dose ranged from 15 to 200 mg., the mean daily dose being 90 mg. for the men and 40 mg. for the women.

There was marked improvement in 28 patients, moderate improvement in 19, slight improvement in 4 and no improvement in 19. Five were treated for less than 10 days which was considered too short a time for adequate evaluation; 9 patients in whom the drug was stopped because of side reactions were included in this evaluation.

The number of side reactions totaled 55, 19 patients having 1, 9 having 2, and 6 having 3 reactions. These side effects were reversible in all instances following either reduction in dosage or cessation of piperacetazine or use of antiparkinsonian compounds. Drowsiness and sedation were common with high daily doses (100 to 200 mg.), and disappeared rapidly when the dose was reduced. Dizziness and syncope occurred in 7 patients early in the study when the starting daily dosage averaged 20 to 30 mg. and did not occur later when the starting dosage was 5 to 15 mg. Pitting edema was noted in 9 women. The edema was distributed in the periorbital region in 1, on the face in 2, on the feet in 2, and on the hands and feet in 4 patients. It disappeared with cessation of piperacetazine, recurring in some but not in other patients when the drug was restarted. An erythematous dermatitis distributed over the face and neck was seen in 5 women. This rash was non-pruritic and subsided rapidly when the drug was stopped, recurring in some patients and not in others when treatment was reinstituted. The edema and dermatitis coexisted in 3 patients.

Akathisia was noted in 1 man and 2 women. The parkinsonian reaction was observed in 3 men who were on high daily doses (200 mg.) of piperacetazine and who

¹ Supplied as Quide by Pitman-Moore Company, Indianapolis, Ind.

² Respectively, Resident Psychiatrist, Staff Psychiatrist and Chief of Research; Napa State Hospital, Imola, Calif.

had been treated for at least 60 days. These extrapyramidal reactions responded rapidly to treatment with antiparkinsonian compounds or to reduction in dosage of piperacetazine. No significant alterations of the laboratory studies occurred in any patient.

In common with other phenothiazine derivatives, piperacetazine was more effective in the hostile, aggressive, hyperactive, anxious and tense than in the regressed, withdrawn or apathetic patient. In addition to its allaying of psychomotor agitation, it reduced such psychotic manifestations as hallucinatory experiences and delusional thinking. The satisfactory daily maintenance dosage ranged from 30 to 100 mg.; daily doses above 150 mg. increased the incidence

of side reactions, particularly drowsiness and sedation, without noticeably increasing the therapeutic effectiveness. No serious side reactions were encountered and the incidence of extrapyramidal reactions was low.

SUMMARY

Piperacetazine, a new phenothiazine derivative of the piperidine series, was clinically evaluated in 75 recently admitted hospitalized psychiatric patients. Its over-all effectiveness in the treatment of the acute psychiatric disorders studied appeared comparable to that of other commonly used phenothiazine derivatives. The incidence of extrapyramidal reactions was low.

WILLIAM RUSH DUNTON, JR.
PIONEER IN REHABILITATION MEDICINE.

A Canadian Tribute

HELEN P. LE VESCONTE, O.T.R.¹

On July 24, 1960, William Rush Dunton, Jr., M.D., celebrated his ninety-second birthday. To him occupational therapists the world over owe much. In the May-June issue of the *American Journal of Occupational Therapy*, members of that Association have paid their tribute to Dr. Dunton whom many of them have been privileged to know as a wise counsellor, a staunch friend and an outstanding physician.

To Dr. Dunton, one of the founders and first president of the National Society for the Promotion of Occupational Therapy, (now the American Occupational Therapy Association); founder and for over 20 years editor of the *Archives of Occupational Therapy & Rehabilitation*, and since 1947 the *American Journal of Occupational Therapy*; author of the first text books on this subject, Canadian occupational therapists may also pay their tribute.

Many Canadian therapists who have not known Dr. Dunton personally, have known him through his writings, for until 1947 when Willard & Spackman published *Principles & Practices of Occupational Therapy*, Dr. Dunton's book *Prescribing Occupational Therapy*, first published in 1928, was the only general text book on the subject used on this continent.

Prior to the writing of this book he had published two text books, *Occupation Therapy* (1915), and *Reconstruction Therapy* in 1919. It was not until 1917 that the term "occupational therapy" was officially adopted, and the older term "reconstruction therapy" continued in use for some years, particularly in the military hospitals of both the United States and of Canada. It is interesting to note that *Prescribing Occupational Therapy* was written as a guide to general physicians. "It has been felt," the author writes in his Foreword, "by those

interested in the promotion of occupational therapy that a more general use of this form of treatment would not be attained until physicians are taught more concerning it and until they know how properly to prescribe its use." Part 1 of this book outlines the general philosophy, principles and the prescription; Part 2 describes the specific application in medical and surgical conditions, orthopedics, tuberculosis, mental disorders, cardiac conditions and pediatrics.

Dr. Dunton's concept and vision of occupational therapy and his concern for the development of professional training and practice were not limited by geographical boundaries. Nor was his chief concern its application in the field of mental disorders in which he has had a long and distinguished career. Of his great contribution in this special field there is no need to write here. It is in the wider field of physical disability that his contribution has been of special importance. His keen appreciation of what total rehabilitation involves, his knowledge of what pioneering physicians, therapists, psychologists and vocational counsellors were doing and thinking, the accurate dissemination of this knowledge through his books and the professional journals—these were the significant things.

Around 1915 there was a keen awareness in both Canada and the United States of the potentials of rehabilitation. In *Reconstruction Therapy* for example, several references are made to the "remarkable work" done by the Canadian Military Hospitals Commission, under the direction of Mr. T. B. Kidner of Alberta, in the development of vocational rehabilitation. Dr. Dunton had become deeply interested in the work of Dr. Herbert Hall, who even prior to 1915 published a number of articles on the problems of the tuberculous patient, particularly in the area of vocational rehabilitation. In these articles and studies Dr. Hall constantly stressed the importance

¹ Division of Rehabilitation Medicine, Faculty of Medicine, University of Toronto, Ont.

of work conditioning and pre-vocational assessment. Both in his books and in the early issues of the *Archives of Occupational Therapy*, Dr. Dunton also drew attention to the work of Frank B. and Lillian Gilbreth on energy conservation and the effects in industry of reduction of fatigue in workers by the elimination of useless motions. These studies were based on observations, made through motion pictures, of the actions of different workers doing the same type of work. Dr. Dunton immediately saw the significance of the Gilbreths' work to the occupational therapist. He emphasized the therapist's need to know the "feel of the tool," and how it is used, and to analyze these features in detail. He stressed the importance of ingenuity in adapting the apparatus used to restore particular movements; that substitution of good muscle must be guarded against in treatment; and that always in treatment the "method of work is more important than the work itself."

For the individual handicapped by loss of a limb, Dr. Dunton recognized the fundamental importance of what today, we term "activities of daily living," when he pointed out that the first need was the formation of habits compensating for the loss; 1—toilet, dressing and washing; 2—feeding oneself easily and comfortably; 3—if necessary, re-education in movements to aid in one's vocation, or to a new one to which he is better suited, by means of pre-vocational training. In *Reconstruction Therapy* he devoted a chapter to the work of Dr. Jules Amar of France, in the development of more functionally useful prostheses. This chapter contains some 20 photographs of terminal devices to facilitate carrying out of self-help activities and for various types of work. These devices are remarkably similar to those used today in the prosthetic training of the industrial accident patient. This chapter also includes an interesting section on the methods and devices developed by Judge Quentin Corley of Dallas, Texas. In 1905 Mr. Corley was severely injured and as a result lost his right arm, scapula and clavicle and also his left hand. Through his own ingenuity he evolved a device which enabled him to carry out all acts of self-help,

e.g., to write, fold and place a letter in an envelope, pick up large and small objects, drive a car, swim, dive and bowl.

As founder and editor of *Occupational Therapy & Rehabilitation*, Dr. Dunton set a standard of professional journals which is impressive both in the quality of the material and the variety, and which he consistently maintained. The first volume was published in 1922 in 6 bi-monthly issues, and in the first two volumes are found articles on 26 subjects which include, in addition to those dealing with medical, surgical, orthopedic and mental disorders, home service and disabled homemaker training, industrial accidents, pre-vocational and vocational training, sheltered employment, music, drama, and recreation as therapeutic media, training of personnel, administration and organization, records, research, the relationship of the occupational therapist to the visiting nurse, the social worker, and in the community and general welfare problems. Constantly there is emphasis on the importance of vocational rehabilitation and the use of activities which provide new channels of economic value for patients who require partial or complete re-education.

One need scan only briefly the writings of Dr. Dunton, to see how clearly he had envisaged and identified the total rehabilitation concept, and the place and contribution of occupational therapy throughout treatment, in the development of orthotic devices and self-help training, in prosthetic training, in pre-vocational assessment, and long range planning for the patient.

William Rush Dunton is indeed one of the important pioneers in the teaching, preaching and practice of rehabilitation medicine. As a mouthpiece of physicians, occupational therapists and above all their patients, he has left a record of the development of these areas which today is a "favoured child" of physical and mental rehabilitation. More truly we should say the *foster* child, for when it was conceived history does not record. But over 40 years ago Dr. Dunton had recognized it as one of the great challenges and responsibilities for those who truly seek to serve the sick and disabled.

COMMENTS

CHILD PSYCHIATRY IN JAPAN

Child psychiatry has made rapid advances in Japan in the past few years. These have culminated in a series of events which indicate vigorous activity and promise of major contributions. In January 1960, the first issue of a quarterly, the *Japanese Journal of Child Psychiatry*, was published; the editorial board is made up of not fewer than 65 members. At the invitation of the editors, Leo Kanner contributed a Note of Welcome. The papers are, of course, written in Japanese but to each article an English abstract is appended. The table of contents of the first issue may serve as an illustration of the range of interests and research topics: Perspective of Child Psychiatry in Japan; A Psychopathological Study of Daydreaming in Early Child Schizophrenia; Case Report of Childhood Schizophrenia, with a discussion of its genesis and classification; A Study of Obsessive-Compulsive Phenomena in Childhood; Psychic Symptoms, especially the Autistic Tendency, of Mentally Retarded Children; Mechanisms and Factors Contributing to the Formation of Childhood Mutism; The Development of Language in Infants. Two additional issues have appeared to date. The second is devoted largely to various aspects of mental deficiency; the third, besides a number of articles on drug treatment, play therapy, genetic factors, stuttering, and schizophrenia, contains a symposium on experiences in the management of psychiatric clinics for children. The papers are of high caliber and would do honor to an American

journal of child psychiatry—if we had one. Most of them come from psychiatric departments connected with (11) medical schools, a few from departments of education and of psychology, several from the National Institute of Mental Health, and one each from departments of obstetrics and pediatrics, and two from the Institute for Physical and Mental Health of Mothers and Children. Every one of the three issues contains abstracts of selected articles from the literature in other countries.

During 1960, also, Drs. Makita (who has had his training in child psychiatry at the Johns Hopkins Hospital) and Kuromaru have completed the Japanese translation of Kanner's *Child Psychiatry*.

It was felt for some time that the growing interest and the increasing number of workers in the field called for an opportunity for nation-wide collaboration. This was done in a number of annual meetings, the last (third) held early this year at Kurume Medical College under the chairmanship of Prof. Kuromaru. However, as the next important step, the leading men in Japan are now in the process of organizing the Japanese Association of Child Psychiatry at a meeting in Tokyo on November 17 and 18, 1960, under the aegis of Professors Kuromaru, Makita, Takagi, and others. This official act brings our Japanese colleagues definitely into the international family of child psychiatrists. Needless to say that they are assured of a cordial welcome.

L.K.

BELIEF

There's no belief so settled as not to be exposed to further inquiry. . . —JOHN DEWEY

CORRESPONDENCE

PSYCHIATRISTS IN CORRECTIONAL INSTITUTIONS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : In the September 1960 *Journal*, pp. 272-273, I note the comments about Dr. Warren S. Wille's article on "Psychiatric Facilities in Prisons . . .," which appeared in the December 1957 issue. James A. McCafferty states that "the only previous survey was done by Dr. Winfred Overholser in 1926," which indicates that the literature was not adequately covered.

In 1932, while I was Director of Classification for the New York State Department of Correction at the Elmira Reformatory, the Salmon Memorial Committee of the New York Academy of Medicine gave me a grant to carry out a study of psychiatric

work in prisons throughout the United States, towards the possibility of preparing a textbook on the "Classification of Prisoners." A survey was carried out on every prison in the United States, and the textbook was written. Also the results were summarized in a paper presented before the New York Academy of Medicine on December 12, 1933 and were published in the *American Journal of Orthopsychiatry*, April 1934.

Unfortunately, psychiatric work in prisons since that time has been more or less at a standstill.

James L. McCartney, M.D., LF APA,
Garden City, N. Y.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : Dr. McCartney appears to have quoted a part of a sentence in my letter that should be attributed to Dr. Wille's paper, namely : "The study by Dr. Wille indicates that his project covered the year 1954 and that *the only previous survey was done by Dr. Winfred Overholser in 1926*" Dr. McCartney gives me undue credit for the underlined portion of the statement. This infers that I overlooked other literature on the subject of psychiatric personnel in correctional institutions.

My letter was not aimed at providing a list of prior surveys but merely to indicate that national statistics on psychiatric personnel in correctional work have been available for many years in the National Prisoner

Statistics series published by the Bureau of Prisons.

Incidentally, besides Dr. McCartney's material, and doubtless many other references, Dr. Norman Neiburg, Director, Division of Psychological Research and Legal Medicine, 33 Broad Street, Boston, Massachusetts recently completed an inventory on psychiatric, psychological and psychiatric social worker personnel employed in State and Federal correctional institutions.

In this discussion perhaps we have overlooked an essential point, the need for more psychiatrists in corrections. Perhaps our combined efforts will attract some of your readers to this important endeavor.

James A. McCafferty, Criminologist,
Research and Statistics Branch,
United States Department of Justice.

DIAGNOSES ON INSURANCE PAPERS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : During the past few years there has been a marked trend towards the inclusion of psychiatric treatment under medical and hospital insurance policies. This has been a

most welcome development, but it has not been without its problems.

One of the difficulties that frequently arises is that the completed insurance form has to pass through the place of employment of the patient and either has to be

filled in by the employer or must be forwarded by them to the main office of the company. Additionally, many forms have to be given directly to the patient.

Under these conditions, it is most difficult to keep the nature of the patient's illness confidential. Certain diagnoses would tend to spread alarm among the patient's business associates and might even endanger his job security.

A solution suggested to me by a colleague, Dr. William F. Gibbs, overcomes this problem in a simple, straightforward way. Instead of writing in the

diagnosis of the patient's psychiatric condition, the official code number of the illness is substituted. This has worked extremely well. On a few occasions, an insurance company has contacted me for clarification, but otherwise, there have been no problems associated with this solution.

Perhaps other psychiatrists would wish to adopt this simple measure as a more or less standard procedure for the completion of insurance forms.

Michael J. Keith, M.D.,
Norfolk, Va.

IS PSYCHOTHERAPY A SCIENCE ?

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : The stimulus to write these lines came from a book *Psychotherapists in Action*. I had to write a review of this book for *Psychiatria et Neurologia*, and am not going to review it here. The author, Hans H. Strupp, is anxious to emphasize the difference between the research psychologist and the psychotherapist. He is a research psychologist.

This is not the first and probably not the last attempt to turn psychotherapy into a science. Many persons seem still to harbor the idea that psychotherapy would be "really respectable" if it were a science. It is understandable, yet not logical, that a psychologist who considers his work as research on psychotherapy, essays an approach through the use of scientific methods. The absurd implication might be made that any field of knowledge and/or practice could be "scientified" by the sheer application of scientific methods. It is almost embarrassing to remind our colleagues of this fact: it is not the methodology which "makes" a discipline a science; it is the approachability of the field concerned which is at the root of this qualification.

Psychotherapeutic practice is basically support of one person by another—that is, in general, of a patient by a psychotherapist. This support demands confidence and respect on both sides. Support, confidence, respect and other subtleties make the "interaction" possible—none of them is measur-

able. Strupp appears to comprehend this, for he writes: "In order to expand scientific knowledge of the therapeutic process, it is necessary to objectify essentially subjective experiences, but as one succeeds in doing so, one runs the danger of sacrificing the essence of what one is studying."

Nevertheless he used his scientific methods, and he still seems to hope to do better in the future, heroically essaying to overcome his unmistakable and not inconsiderable frustration which, incidentally, is also not measurable.

We have been doing psychotherapy in our professional life as well as we could. We realize its indispensability. This realization is one of the reasons for which we cannot remain mute with respect to all the claims made concerning psychotherapy. We, the psychiatrists, have to plead guilty as regards the development psychotherapy was allowed to take in theory and practice.

Since we consider support the core of any psychotherapy, we might be suspected of holding that everybody can learn and teach it well enough through some good drilling and training. This is not our opinion. We are, indeed, convinced that the ability to teach and the ability to learn psychotherapy are quite limited. Regardless of all the discussions on learning psychotherapy and, regardless of the increasing number of places where training is being offered, one point ought not to be forgotten. There is something in psychotherapy that cannot be either taught or learned. Sir William Osler had "it"

without ever going through any psychotherapeutic school. Call it intuition or fingertips or what else you want, this "it" is on the same level as the creative gift of the artist—the gift which distinguishes the artist from the dilettante and the amateur. Some call it the divine spark—why not?

If one remembers this, one cannot but be sadly amused about the endeavor to get

hold scientifically of "interaction"—rewriting practically the volumes about it that only recently have been studied on the subject of transference. Perhaps the time will come when all this will be moderately well understood, though not scientifically analysed, under the modest label of rapport.

Eugen Kahn, M.D.,
Houston, Texas.

REVISED SURVEY OF SELECTED PSYCHOPHARMACOLOGICAL AGENTS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : In the November, 1960 edition of the *Journal*, Cattell and Malitz have a review of the "Revised Survey of Selected Psychopharmacological Agents." They include a statement concerning prochlorperazine (Compazine SKF). They report that there have been no instances of jaundice with this drug. This is not the case. I have seen 2 patients who have had marked jaundice associated with the administration of Compazine. In both instances the jaundice was self limited and cleared after the removal of the drug. In one patient the jaundice appeared on the seventh day of treatment. In the other patient it did not appear until 2 months following the onset of Compazine therapy. In both instances there could be

no confusion as to the etiology, for the patients were on no other medication and careful clinical and laboratory studies were not indicative of other etiologic sources.

From a laboratory standpoint, one of the patients showed the following : Serum bilirubin, 5.3 mg.%, 4+ bile in urine, serum protein partition studies reveal no abnormalities, Serum alkaline phosphatase, 15K.A. units, cephalin flocculation and thymol turbidity negative. Prothrombin 17 seconds (normal 14). Other blood studies were in a normal range.

I would like to record this information to avoid any confusion in the minds of your readers.

Stanley Lesse, M.D.,
Neurological Institute of New York,
New York 32, N. Y.

OFFICIAL REPORTS

REPORT OF THE COORDINATING COMMITTEE ON PROFESSIONAL STANDARDS IN PSYCHIATRY

1. The first committee of this group is the Committee in Liaison with the American Academy of General Practice, which has functioned under the chairmanship of Dr. Robert Matthews. This committee has been working jointly with the Mental Health Committee of the American Academy of General Practice and has maintained both formal and informal communication with members of that committee throughout the year. There is a General Practitioner Education Project in the office of the Medical Director of the American Psychiatric Association with a director, Dr. William F. Sheeley. Dr. Sheeley and the committee have worked closely together.

The committee has used all channels of communication available to it including articles in the journal *Mental Hospitals* and the *APA Mailpouch*. It is exploring the use of State Hospitals as a locale for courses in psychiatry for general practitioners. It has worked closely with the out-going Speaker of the Assembly of District Branches and has made use of the communications machinery which he has set up.

It is gratifying to report that there is a high degree of interest in the Academy of General Practice in the problem of post-graduate psychiatric education for general practitioners. It is, however, distressing to report that this interest is considerably higher in the AAGP than in the APA. The Committee sees a need to point out to the members of the APA that they have a responsibility to undertake joint teaching activities with local units of the AAGP; assures them that they will derive much personal satisfaction and professional advantage from such relationships; and hopes that they will make every effort to correct this discrepancy of interest.

2. The Committee in Liaison with the American Hospital Association has operated under the chairmanship of Dr. Raymond Waggoner. This Committee has been extremely active. There have been two

meetings jointly with the corresponding Committee of the AHA since our own Committee meetings in Detroit last fall. The Committee has completed its work on the brochure "Psychiatric Units in General Hospitals" which is to be published by the AHA after approval by the Council of the APA. The brochure is being presented to the Council on Thursday for its approval.

The Committee has also been concerned with the growing development and expansion of psychiatric units in general hospitals and with potential difficulties which may come up in relation to involuntary detention in locked facilities in such units. It has a resolution pertaining to such detentions and proposes to present this to the Council for action and approval.

3. The Committee on Mental Hospitals. This Committee has been chaired by Dr. Joseph E. Barrett. It has been concerned in the past year, as it has in previous years, with the problems which confront the mental hospital at this moment in a changing culture in relation to mental hospitals. The Committee was somewhat critically concerned with a brochure on general principles and guides for psychiatric units in general hospitals prepared by the office of the Medical Director and has worked with him to produce modification of this in a direction more satisfactory to everybody concerned. It has continued to deal with the many problems that confront the mental hospitals of the nation.

4. The Committee on Nomenclature and Statistics is another of our hard-working Committees which operates under the chairmanship of Dr. Moses Frohlich. It has held several meetings in addition to the usual fall meeting held by most of our committees. This Committee has just now completed revision of the classification and nomenclature for the 1960 edition of the A.M.A. "Standard Nomenclature of Diseases and Operations." It will be of interest to the members of the Association that al-

though a great deal of work has been done by the Committee, and a thorough review made, the revisions proved necessary were found to be relatively minor in degree and few in number.

The Committee has come also, during this year, close to completion of the revision of the Diagnostic and Statistical Manual published by the APA. There has been an attempt to sharpen the objective criteria for classifying and to improve uniformity in the use of the classifications.

The third major project of the Committee has been to work on the preparation of a manual on "The Gathering and Use of Data in Psychiatric Facilities" but this has been largely in abeyance due to the pressure of revision of the "classification." Further work will need to be done on this and it is hoped that this can be completed soon.

5. The Committee on Private Practice, under the chairmanship of Dr. John Cotton, has continued its extremely important and interesting work. It has been concerned in the last several years with the question of health insurance for psychiatric illness. It is gratifying to report that there seems to be now a definite trend throughout the country to include psychiatric care in hospitalization insurance. This has been in part due to the increasing number of psychiatric services in general hospitals. There are now almost 1000 such units and many more planned and it appears to the Committee that this is the most important development in the past 15 years to concern the private practice of psychiatry. The Committee continues with its plans to make a study of the variety of services offered by general hospital psychiatric units, and hopes to obtain funds from private sources to finance such a study.

6. The Committee on Psychiatric Nursing has been headed by Dr. Granville Jones. This Committee has worked with equivalent groups from the Nursing Organizations and has continued to seek more exact definitions and more comprehensive ideas of psychiatric nursing and the function of the psychiatric nurse. As you are well aware, the role of this particular one of our professional colleagues is currently undergoing changes, and the Committee hopes to continue to explore what these role changes

are and how to clarify them. There is some thought that a general conference on this topic might be helpful.

This Committee recognizes that it deals with only one of the many disciplines involved in patient care but because the National League for Nursing and the American Nurses Association have suggested it, this Committee is prepared to urge that the APA call a multi-disciplinary conference to explore means of improving total patient care with particular emphasis on in-service education.

Under the general aegis of your Committee the seminar project for teachers of psychiatric aides was set up. This project is now approaching completion. The seminars have all been held and the director and the psychological consultant are analyzing the results preparatory to writing a full report. Your Committee believes that this has been a most successful venture and trusts that the report will be a real contribution to the literature on aide education.

7. The Committee on Psychiatric Social Work has been extremely active. Dr. Maurice Friend as chairman has stimulated his Committee into many fields of activity. The Committee has kept close contact with various individuals and consultants from the National Association of Social Workers, Psychiatric Section, and has made use of the *Social Workers Newsletter* for communication. It has also been in contact with our own District Branches.

The Committee on Psychiatric Social Work is aware of the proposal reported immediately above for a conference on patient care and expresses its interest in participating in such a conference.

At several places, sub-committees on psychiatric social work are working closely with the parent Committee. The parent Committee is watching also with interest and helping in any way it can in certain special studies being carried out by local sections of the National Association of Social Workers.

Finally, but not least, the Committee has been very much concerned with the problem of recruitment of personnel into the social work field.

8. Your Committee on Psychiatry and the Law (you will note the change of name

which was authorized last year) has been chaired by Dr. Louis Gendreau. This Committee has been for some time concerned with the problem of privilege in the relationship between psychiatrist and patient, with commitment laws and their uniformity and with other matters that involve the many intriguing inter-relationships between psychiatry and the law. While it has not been able to make many very specific recommendations, it feels it is having an effect on many of these matters in many states and is pleased to report that at least one state has now adopted a statute which gives privilege to the relationship between a psychiatrist and his patient in therapy.

9. One of the most important committees of your association in view of the present cultural and social situation is that on Relations with Psychology. Dr. Joel S. Handler, taking over this Committee only a year ago, has done a great deal to ease some of the difficulties between us and our colleagues of the other APA. Meetings have been re-established with the other group after a break in communication of two years. A statement has been prepared, approved by Council and published in the *Journal* of the APA. Discussions will continue of such basic issues as medical responsibility for the welfare of the patient, the question of the independent practice of psychotherapy by the psychologist and the matter of local liaison between District Branches of our APA with their opposite numbers in the State Psychological Societies.

The Committee feels very strongly that legislation is not the answer to any of the problems of either of the APAs. It feels rather that there must be continuous free communication and discussion, so that there can result a final implementation, by a continuous process of joint responsibility, of training in the ethical problems involved in the relationship of the two professional disciplines at local levels. The Committee believes that some of the chill which was developing between the two disciplines has been dispelled by its activities. Dr. Felix, our incoming president, has been most interested in this problem, and has worked with the Chairman of the Committee and with the full Committee on several occa-

sions in an attempt to solve the complex problems which have come up.

10. The Committee on Standards and Policies of Hospitals and Clinics, has been chaired in the past year by Dr. T. Stewart Ginsberg. This Committee has worked in two basic fields: hospitals and clinics. At the same time, however, it has recognized many recent changes in the situation and the need for a complete re-evaluation of the whole matter of Standards and Policies for both hospitals and clinics. It has prepared a proposal for a long and detailed study of the matter with conferences and exchange of ideas and is in process of seeking support for such a project which it is hopeful it will obtain in the near future.

11. One Ad Hoc Committee, that on An Organization for Mental Hospital Personnel, under the chairmanship of Dr. Marion Kenworthy, has also reported to this Coordinating Committee. The problems involved have been discussed at a number of meetings and recommendations made to the Council. The basic recommendation has been that such a group be tried out on a pilot basis at a local level, in relation to a Divisional Meeting, and it is hoped that implementation of this recommendation will soon occur.

In such a brief period today it is difficult to give you more than a suggestion of the amount of work and thought that has gone into the Committee activities in the past year. Since this marks the termination of my assignment as Coordinating Chairman of this group of Committees, I should like to take this opportunity to thank all of the Chairmen and Committee members who have made, in the past several years, my job so much easier than it might have been. I should like to thank the Medical Director and his Staff and the Executive Assistant and his Staff for invaluable assistance. The officers of the Association, over the several years, have had a clear understanding of what committee work and coordinating committee work ought to be and, of course, it has been possible to work collaboratively and cooperatively with all of them. The Coordinating Chairmen of the other two groups have been, and I hope will continue to be, my friends as well as my collaborators in this total committee effort.

Because I am now leaving this position, I should like to take the opportunity to say to you how important and how useful I think this technique of the establishment of coordinating committees has been for the work of the Association. You will recall that it was in the presidency of Dr. John Whitehorn that these Coordinating Committees were set up, on the basis of a recommendation made by the Committee on Com-

mittees, which studied the whole matter under the chairmanship of Dr. Robert H. Felix. After years of experience with this I simply wish to take the chance to say that I believe this was a brilliant concept that has worked extremely successfully for the benefit of the over-all work of the APA.

Wilfred Bloomberg, M.D.,
Chairman.

AS YOU LIKE IT

It is honor enough to be read and studied, even if only to be combatted ; and I send my critics back to their respective camps with my blessing, hoping that the world may prove staunch and beautiful to them, pictured in their own terms.

—SANTAYANA

WHAT LIVES ON

Immortality is a word that Hope through all the ages has been whispering to Love. The miracle of thought we cannot understand. The mystery of life and death we cannot comprehend. This chaos called world has never been explained. The golden bridge of life from gloom emerges, and on shadow rests. Beyond this we do not know—Fate is speechless, destiny is dumb, and the secret of the future has never yet been told. We love ; we wait ; we hope. The more we love, the more we fear—upon the tenderest heart the deepest shadows fall. All paths, whether filled with thorns or flowers, end here. Here success and failure are the same. The rag of wretchedness and the purple robe of power, all differences and distinction, lose in this democracy of death. Character survives ; goodness lives ; love is immortal.

—ROBERT C. INGERSOLL

NEWS AND NOTES

TRAINING IN PSYCHIATRY FOR PRACTITIONERS OF MEDICINE.—Philadelphia General Hospital has been approved by the National Institutes of Health, U. S. Department of Health, Education and Welfare for an annual grant for graduate training in psychiatry.

The grant allows for training general practitioners or other physicians in psychiatry, and is for a maximum \$12,000 a year. Interested physicians make dual application to both PGH and NIH.

Dr. James R. Harris, chief of psychiatry at PGH states that the NIH set up this type of grant to train practising physicians who wish to go into psychiatry, but cannot afford to make the change without compensation other than regular residency salary.

CONFERENCE ON NEUROPSYCHOPHARMACOLOGY.—This conference was held in New York City on November 12 and 13, 1960. Clinical psychiatrists, educators, researchers in basic sciences as well as clinical investigators participated. The Chairman of the conference was Paul H. Hoch, M.D., N. Y. State Commissioner of Mental Hygiene.

Among the recommendations was that a new society be formed, with the purpose of advancing knowledge in this important area of psychiatric research. An organizing committee was appointed, with Dr. Theodore Rothman of the University of Southern California School of Medicine as Chairman.

It is probable that the new society will be organized in time for the May meeting of the American Psychiatric Association.

PANEL DISCUSSION OF "DISTORTED COMMUNICATION."—This symptom in the psychoneurotic will be the subject of a panel discussion under the auspices of the Association for the Advancement of Psychoanalysis on Wednesday evening, February 15, 1961, 8:30 p.m. at the New York Academy of Medicine, 2 E. 103rd. St., New York City.

The speakers are Dr. Dominick A. Barbara, Dr. Martin Symonds, Dr. Robert L.

Sharoff, Dr. Joost A. Meerloo, Dr. Jack L. Rubins, Secretary of the Association will be the Panel Moderator.

TEACHING BEHAVIOURAL SCIENCES AT ALBANY MEDICAL COLLEGE.—An undergraduate teaching program in behavioural sciences has been established at the Albany Medical College of Union University as a sub-department of the college's department of psychiatry. Dr. Frederick D. McCandless, associate professor of psychiatry and former head of Albany Hospital's psychiatric outpatient clinic heads the new sub-department.

The course will be presented to students during their first 2 years of medical training, beginning September, 1961. Its purpose will be to integrate and expand teaching in such subjects as psychology, sociology and anthropology, especially in their application to the understanding of health problems; and thus enable future physicians to consider more fully the psychologic and sociologic aspects of their patients' illnesses.

EASTERN PSYCHIATRIC RESEARCH ASSOCIATION.—This Association will hold its 25th Scientific Meeting on Thursday, February 2, 1961 at 8:00 p.m. at the New York University Medical School, 30th St. and 1st Ave.

The speakers will be Anthony Sainz, M.D., Marcy, N. Y., Theodore R. Robie, East Orange, N. J., and William L. Holt, Jr., Albany, N. Y.

IV REUNION ANUAL DE LA SOCIEDAD DE NEUROCIRUGIA DE CHILE.—This Conference will take place on June 2 and 3, 1961, at Santiago, Chile under the presidency of Dr. Carlos Villavicencio.

The subject of the Conference will be "Tuberculosis of the Central Nervous System." All aspects of tuberculosis of the central organs in children and adults, including atypical forms and sequelae will be discussed by an outstanding group of speakers.

BOOK REVIEWS

THE CENTRAL NERVOUS SYSTEM AND BEHAVIOR. Transactions of the second conference, February 22, 23, 24 and 25, 1959. Edited by Mary A. B. Brazier. (New York: The Josiah Macy, Jr. Foundation. \$4.75.)

This volume is an excellent example of the product of a multi-disciplinary approach to a most complex subject. The limbic system constitutes the major consideration in this text.

Dr. Paul D. MacLean (National Institutes of Mental Health, Bethesda, Maryland) is responsible for the chapter relating the function of the limbic system to self-preservation, and preservation of the species. Dr. Endre Grastyan (University of Pécs, Pécs, Hungary) is responsible for the chapter on the hippocampus and higher nervous activity, and in approximately 80 pages, he discusses the part played by this portion of the central nervous system in conditioning mechanisms, memory and learning. The subject of "temporary connections" receives a thorough consideration. It would appear the conference suggested the functions of the limbic system involved preservation of the individual, preservation of the species, programming of activities and relating present activity to experience.

It might be of interest to those of us who have been primarily interested in the reticular system of the brain that in discussing the limbic system in this volume, a suggestion was made that the reticular system might be included as part of the "limbic" system.

Dr. Jan Bures (Academy of Sciences, Prague, Czechoslovakia) is responsible for the chapter on reversible decortication and behavior. In this chapter, "functional" as well as anatomical decortication is discussed, and the conditional reflex, depression and inhibition are considered.

Vladimir S. Rusinov (Academy of Sciences, Moscow, USSR) is responsible for the chapter on EEG studies in conditional reflex formation in man. Here again "temporary connections" and their site is a subject thoroughly considered, including the role of the cortex, sub-cortex, reticular formation, limbic system, thalamus, etc., in this function.

Dr. Brazier contributed the last chapter, reporting her impressions of the Colloquium on EEG and Higher Nervous Activity held in Moscow, USSR, October 6 to 11, 1958, in which Dr. Brazier covers the transactions by brief notes and adds her interesting descrip-

tions of the various Russian cities and institutes she visited in connection with this Colloquium.

This volume adds another significant building block to our knowledge of the relationship of behavior to central nervous system function. For those interested in this subject, this volume provides a wealth of information and stimulation. It will serve as another basic reference text in this field of investigation.

EPIDEMIOLOGICAL METHODS IN THE STUDY OF MENTAL DISORDERS. By D. D. Reid. Public Health Papers 2. (Geneva, Switzerland: World Health Organization, 1960, pp. 79. \$1.00.)

Research in psychiatry has much to be thankful for to Dr. Reid for presenting this brief map of the concepts and techniques of epidemiology and its applications in the field of the mental illnesses. There are few ideas necessary for the design of productive studies which are not put forward here. The bibliography is highly selected to offer the reader more information on particular techniques or examples of the points made, thus avoiding loading the text with more than absolute essentials.

One of the useful chapters deals with the definition of the often misused terms, incidence and prevalence and with the variations in their meaning introduced by one or another adjective—"point," "period," "all-life," etc., adjectives too often left out when actually needed for true comprehension of the author's meaning. The basic considerations of population at risk and the opportunities and pitfalls of age standardization are well explained.

The book appropriately gives a great deal of attention to two highly critical points in all psychiatric epidemiology, the matter of sample selection and the problem of the selection of controls. The technique of cohort studies over relatively long periods is gone into rather thoroughly, together with the difficulties of the method.

Reid makes it very clear that the fundamental problem in the epidemiology of mental health and diseases lies in the old question, "What is a case?" It is unfortunate that the Leighton and Rennie studies were not available for consideration in relation to this issue—as well as others, throughout the book.

The World Health Organization, to which Dr. Reid was consultant for this study, published the volume. It represents another unit in what has thus far been a series of excellent publications in the field of psychiatry and mental health. This volume should be on the reference shelf of every experienced worker and on the desk and at hand for every beginner in the field.

THE SILENT LANGUAGE. By *Edward T. Hall.*
(Garden City, N. Y. : Doubleday and Co.,
Inc., 1959, pp. 240. \$3.95.)

THE SYMPTOM AS COMMUNICATION IN SCHIZOPHRENIA. Edited by *Kenneth L. Artiss.*
(New York : Grune and Stratton, 1959, pp.
233. \$6.00.)

Two fine new books on communication patterning call for attentive consideration by psychiatrists and other behavioral scientists. The first is written by an anthropologist with experience in the training of federal government employees for foreign service, a service in which mistakes and ineptitudes have provided material for a vigorously critical nonprofessional literature. Beginning with the observation that standards of behavior appropriate to one societal matrix may be completely misunderstood in another, Dr. Hall outlines an original theory of the nature of culture, treating it consistently as a form of communication. Ten "primary message systems" are described (interaction, association, subsistence, bisexuality, territoriality, temporality, learning, play, defense, and exploitation). The book is written in lucid style and is a fundamental contribution to the science. Its heuristic value is likely to be high.

Dr. Artiss edits the second book, a group study of schizophrenia from Walter Reed Army Institute of Research. The symptomatology of schizophrenia is seen as a communication device in the transactions between the patient and others. The schizophrenic is described as operating within a pattern of dilemmas—dependency preventing independence, omnipotent self-evaluation in the face of failure, hostility provoking retaliation, and avoidance provoking rejection. Within these dilemmas, the symptoms were useful and available reaction patterns "accomplishing" the rejection of the person from the family, from work groups, from the Army group, and from the ward population. The odd and different soldier, per-

forming poorly, unable to make friends and preoccupied with himself, replicated a series of negotiations proven by his past experience to lead to maximum comfort. He reassumed his unique and isolated position, and with the aid of those about him, confirmed his differentness and inability to perform. In hospital, the sought-for position of isolation and persecution could not easily be maintained in the face of very different group pressures. The ward culture sought to avoid a consensus of difference, to avoid relieving him of responsibility for poor performance and failure, to avoid further isolation from effective learning, to avoid confirming with him his non-need to learn. The fundamental function of the psychotic symptom—the avoidance of group status—was not allowed to operate. When the patient was able to "join" the patient or staff group, a reciprocal symptom loss followed. Parallel studies on the families of schizophrenics revealed an atmosphere of chronic, basic discontent. The intra-familial relationships were often improved by the hospitalization of the member in the "sick" role.

These books bring a measure of integration between the fields of information transmission, comparative cultural anthropology, education, and therapy. Both are models of methodology. They will give a refreshing redirection to the clinic worker and to the investigator.

HANDBOOK OF SOCIAL GERONTOLOGY: SOCIETAL ASPECTS OF AGING. Edited by *Clark Tibbitts.* (University of Chicago Press, 1960, pp. 770. \$10.00.)

This important volume represents a first attempt to give form to a new field of research and knowledge—social gerontology. Social gerontology is concerned with (a) the phenomena of aging which are related to man as a member of the social group and of society, and (b) those phenomena which are relevant to aging in the nature and function of the social system or society itself. The contents are as follows: Clark Tibbitts, "Origin, Scope, and Fields of Social Gerontology"; Harry D. Sheldon, "The Changing Demographic Profile"; Leo W. Simmons, "Aging in Preindustrial Societies"; Fred Cottrell, "The Technological and Societal Basis of Aging"; Eugene A. Friedmann, "The Impact of Aging on the Social Structure"; Leonard Z. Breen, "The Aging Individual"; Eugene A. Confrey and Marcus S. Goldstein, "The Health Status of Aging People"; Margaret S. Gordon,

"Aging and Income Security"; Richard H. Williams, "Changing Status, Roles, and Relationships"; Fred Slavick and Seymour L. Wolfbein, "The Evolving Work-Life Pattern"; Wilma Donahue, Harold L. Orbach, and Otto Pollak, "Retirement: The Emerging Social Pattern"; Max Kaplan, "The Uses of Leisure"; Gordon F. Streib and Wayne E. Thompson, "The Older Person in a Family Context"; John W. McConnell, "Aging and the Economy"; George Rosen, "Health-Programs for an Aging Population"; Walter K. Vivrett, "Housing and Community Settings for Older People"; Fred Cottrell, "Governmental Functions and the Politics of Age"; Arnold M. Rose, "The Impact of Aging on Voluntary Associations"; Paul B. Maves, "Aging, Religion, and the Church." There are indexes of names and subject.

A fundamental volume.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

BIOCHEMISTRY OF HUMAN GENETICS. Ciba Foundation Symposium. Edited by G. E. W. Wolstenholme and C. M. O'Connor. (Boston: Little, Brown and Co., 1959, pp. 360, ill. 61. \$9.50.)

Of the 4 anniversary symposia sponsored by the Ciba Foundation in 1959 to mark its tenth year of successful promotion of "international cooperation in medical and chemical research" (London, Buenos Aires, Naples, Paris), that on human biochemical genetics at the University of Naples (May 13-16) was co-sponsored by the International Union of Biological Sciences and chaired by Montalenti. Focused on highly refined laboratory techniques for studying the biochemistry of gene action, the proceedings of this timely and well-organized conference provide an authoritative survey of the remarkable progress which in the analysis of human traits has been made in identifying "the direct line of causation from a genic structure, with known chromosomal location, to the corresponding, visible character." As Penrose emphasizes in the introduction, biochemical methods are now in the ascendant, while statistical arguments about exact Mendelian ratios have become less cogent.

In line with the selective policies of the sponsor, the conference was attended by a limited number of specialists in biochemical and cytological genetics (29 experts from 6 Western countries), with formal papers contributed by 14 of them. The subjects covered include galactosemia (Kalckar); defective sense perception (Kalmus); primaquine sensi-

tivity of erythrocytes (Childs and Zinkham); fetal and abnormal hemoglobins (Rossi-Fanelli, *et al.*, Itano, *et al.*, Hunt and Ingram); the synthesis of the haptoglobin system (Smithies and Connell), gamma globulin molecule (Grubb) and specific blood group substances (Morgan, Watkins, Ceppellini); and the genetic control of cholinesterase concentrations (Kalow) and plasma protein variants (Harris, *et al.*). Each section is followed by the transcript of an animated group discussion, thus aiming at presenting a well-rounded picture of the current state of knowledge in important frontier areas begging for the collaborative efforts of the biochemist, cytologist and geneticist.

The last part of the book deals with a panel discussion of technical problems encountered in bacterial genetics and modern tissue culture work (Luria, Cavalli-Sforza, Eagle, Lederberg, Pontecorvo). Of particular interest are the questions raised by Eagle regarding the immediate usefulness of observations derived from cultures of dispersed cells as distinguished from explant cultures of organized bits of tissues. While cultured cells show a remarkable degree of uniformity in their nutritional requirements, they tend to use their metabolic machinery for purposes of growth rather than the desired differentiation of specialized organ function.

As an age-specific growth record of a dynamically developing discipline with a bright future, this book will be of intrinsic merit and bibliographic interest for many years to come. It is carefully edited and upholds the fine standards set by publications of the parent organization. The only disappointing feature is the immoderate price difference between the English and American editions.

FRANZ J. KALLMANN, M.D.

MENTAL HEALTH, THE NURSE AND THE PATIENT. By Doris M. Odlum. (Philadelphia: J. P. Lippincott Co., 1960, pp. 190.)

This book has been adapted by Miss Ethel Johns from the third edition of the book *Psychology, the Nurse and the Patient*.

The author deals with the psychological aspects of illness. The first few chapters deal simply and briefly with a general psychological approach.

The next chapters apply psychology more specifically to a number of situations which arise in nursing. These situations which Miss Odlum has chosen are practical and applicable in many areas. In this edition greater emphasis is placed on the patient outside of hospital.

In the last few chapters of the book there is a brief discussion of the psychoses and the psychoneuroses including methods of treatments. The role of the nurse in the care of the mentally ill patients is considered.

The book is short, easy to read and the illustrations generally are applicable to our situations. The presentation and choice of material at times appear uneven. The book would be a useful reference on an elementary

THE ANTECEDENTS OF MAN. By W E. Le Gros Clark. (Chicago : Quadrangle Books, 1960, pp. 374. \$6.00.)

Knowledge relating to the physical evolution in man has increased apace in recent years. In the present volume one of the soundest students and most lucid writers on man's evolution presents the facts which will lead the reader to a thorough understanding of the antecedents of that ornery creature, so prematurely named *Homo sapiens*. The book is excellently illustrated, and since the author is a leading neuroanatomist, his discussions of the evolution of the brain and special senses are particularly stimulating.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

DREAMS AND PERSONALITY DYNAMICS. By Manfred F. DeMartino, M.A. (Springfield, Ill. : Charles C Thomas, 1959, pp. 377.)

This book is a compilation of 28 articles of theoretical, clinical, empirical, experimental and statistical nature, proposed to be of interest and value not only to students, psychological clinicians, and those who practice dream analysis, but also to academic psychologists. The editor hopes to stimulate interest in dream research to fill in gaps that are present in personality theory. The papers are selected from a period of American research from 1930 to 1958. Only one foreign paper is included, by Boss. All the papers have been previously published with the exception of one which is a doctoral dissertation. (One exceedingly valuable footnote in the book lists a number of unpublished masters' and doctoral theses on dream analysis.) Almost all of the papers have been abridged. Curiously enough a valuable feature for further study and research has been omitted, namely, the bibliographies at the end of each paper.

An editor must, from the vast literature on the subject, choose only a certain number of papers which he considers representative of the field ; therefore, a certain amount of arbitrariness enters into his selections. For what DeMartino intended for his book he has done rather well. Some outstanding papers are included : the excellent paper on "The Dreamer" by Gardner Murphy and Calvin S. Hall's "Cognitive Theory of Dreams."

I happen to find particularly interesting and informative Harry B. Weiss's "Oneirocritica Americana" on the 18th and 19th century American "Dream Books"; McCurdy's "History of Dream Theory" systematizing the approaches of ancients towards the study of dreams, a worthwhile elaboration of Freud's remarks about ancient dream interpretation. The editor's "Review of the Literature on Children's Dreams" is valuable.

Following the introduction is a section on empirical and statistical studies, including one chapter on "Nocturnal Sex Dreams" by Kinsey and his associates. Then follows a section on experimental and theoretical studies with papers by Irving Harris and Calvin Hall on anxiety dreams. The section on "Personality Correlates of Dreams" consists of 4 papers : Meer's "Authoritarian Attitudes in Dreams," Saul's and his associates' paper on the "Quantifications of Hostility in Dreams," Doust's "Studies in Physiology of Awareness" and Boss's "Psychopathology in Dreams in Schizophrenia and Organic Psychoses."

The section on methods of dream analysis is rather mixed. The paper by Hall on diagnosing personality by analysis of dreams is quite good especially because it contains a section on methods of validation. Of the host of papers in the last 30 years on dream analysis, why the one on the technique of dream analysis by Otto Kant was selected for publication is not altogether clear, since there are numerous papers more representative of recognized meaningful methods than the ideas presented by Kant's paper. This reviewer is still at a loss after several readings to understand what Kant means by saying that a "dream should be interpreted as little as possible, it should be read."

The section on the use of hypnosis includes the by now classical paper by Leslie H. Farber and Charles Fisher, and the excellent "Dreams and Hypnosis" by Margaret Brenman. The longest paper in this section is quite an abridged version of David B. Klein's study of 30 years ago on the experimental production of dreams during hypnosis. I suppose one of the values for the inclusion of this latter un-

imaginative work is that it is not too well known.

The last section reprints papers on dreams and projective techniques and on the physiological correlates of dreams, the latter containing the well known papers by Dement, Kleitman and Wolpert.

As one can note from the above, the book is eclectic and has therefore the advantages and disadvantages of such an approach. It is useful as a reference source, but might have been more so.

NORMAN REIDER, M.D.,
San Francisco, Calif.

PRACTICAL NEUROLOGICAL DIAGNOSIS. By R. Glen Spurling. (Springfield, Ill.: Charles C Thomas, pp. 284. \$6.75.)

The reviewer is hesitant to be critical of this little book written by a senior neurosurgeon. However, he believes many neurologists and many modern neurosurgeons would not consider it adequate nor sufficiently accurate for their students at any level. The adjective "practical" in the title of any book should not absolve the author from accuracy or from giving adequate detail of the subject under discussion. These points of criticism will be illustrated. Unfortunately, too, the style of writing is lacking in smoothness. The book does not make the clinical correlations with anatomy and physiology sufficiently clear nor does it outline a method of thinking through these correlations. The correlations come mainly in the form of dogmatic statements.

The "Cushing outline" of history and examination has much to commend it but it does emphasize localization at the expense of gathering facts, thinking of disturbed functions and then making interpretations of localization. Unfortunately, tradition and convenience have partly sustained this approach especially with reference to the study of cranial nerves. For example, doctors and students sometimes speak and actually think of facial weakness as something wrong with the 7th nerve even though the causative lesion is in the cortex or in the muscles. This book does not help to correct this erroneous approach. Another error in the outline is to list the sign of Romberg under cerebellar functions. This is a common error but a text should help to correct it. To use this sign in this way makes it meaningless. The methods of eliciting, as well as interpreting, reflexes are inadequately discussed.

In a book devoted to practical considerations one would expect the reader to be guided

quickly to an understanding of how to hear cranial bruits. Important features of auscultation are neglected and no mention is made of what one might call the best listening points over the head. The section on vision leaves much to be desired in every way. Good coloured pictures rather than drawings should be used as illustrations of papilledema. The chapter on lumbar puncture and spinal fluid does not outline the necessary detail which would guide a student either as to the examination of it or interpretation of the findings. Why does the author state that a lumbar puncture should not be done in the office? No mention is made of spinning down the red blood cells, when a bloody tap is obtained, before interpreting the appearance of the fluid. Why not say something of total protein in ventricular fluid as compared with that in the lumbar sac? The reviewer believes it would be wiser to omit the section than omit discussion of generally accepted points of importance in evaluating the study of spinal fluid.

The book is for students, interns and residents, but the reviewer does not believe it fulfills its designated purpose and believes the student and doctor will find more adequate information and more deductive methods of making correlations outlined in many of the standard texts of neurology.

ALAN A. BAILEY, M.D.,
Saskatoon, Sask.

OPERATIONAL VALUES IN PSYCHOTHERAPY. By Donald D. Glad, Ph.D. (New York: Oxford University Press, 1959.)

Despite its rather foreboding title, Dr. Glad has written a most understandable and eminently useful treatise. This volume represents more than a decade of work by Dr. Glad and a devoted coterie of students and associates. Its basic premise is that the psychotherapist's own personal value system will largely determine the "school" of psychotherapy he embraces, the operational procedures he pursues, and the type of therapeutic results he accomplishes. With this in mind, the author explores various aspects of Freudian, Sullivanian, Rankian and Rogerian therapy—as examples of current dynamic schools representing different value systems and different operational rules. The result is a critical second look at many of our cherished and unexplored faiths.

Many psychotherapists, particularly psychiatrists, will read this book with some dismay. It suggests that we may need to broaden our approach to understanding personality and

vary our techniques in psychotherapy from patient to patient. This work may bring to our attention a degree of professional short-sightedness and stir up anxieties and some animosities. The information presented is derived from controlled research and statistical analysis which at times makes difficult reading for the clinician. It may further cause some discomfort to the clinician in questioning the validity of using a single frame of reference in the diagnostic and psychotherapeutic approach to patients. The implications of this book are such as to shake one out of the security of using a single approach in dealing with patients and their emotional difficulties.

Dr. Glad's basic thesis suggests that the closer the patient's initial personality is to the goals of the therapist and the techniques of therapy derived therefrom, the sooner the patient can be expected to progress toward recovery with the latter refined in terms of the patient's achievement of the therapist's goals. Thus Dr. Glad suggests a need for shaping the therapist's theoretically derived method of treatment very early and very perceptively to the personality organization of the patient. This implies a need for careful psychiatric and psychological studies of each patient being considered for therapy and further underlines the need for a great deal of flexibility on the part of the therapist in the therapeutic techniques he applies. It further implies that the psychotherapist must have a broad background in clinical experience using different types of therapeutic approaches to different patients. This has many implications also from the standpoint of psychiatric education and would suggest the need in psychiatric training programs for a truly eclectic and broadly based approach to the teaching of psycho-dynamics and psychotherapy.

For the psychologist and psychiatrist particularly interested in research methodology, one will find the discussion of a technique for the study of change during therapy—a method that is as free as possible from a dependence, in the evaluation of the results of therapy, on our subjective, wish-fulfilling judgments which are so common in the literature today. Using this methodology Dr. Glad has very cogently illustrated and put to careful research test many of the hypotheses he has offered.

The basic thesis is both intriguing and promising and one that can only be worked out by further painstaking research, statistical analysis and follow-up. His readers will wish him the strength and stick-to-it-iveness to continue in this pioneer venture. Only through such works can psychotherapy be put into an

operational frame where it may be objectively studied. Every psychiatrist, psychologist, sociologist and clinician whose work brings them into the therapy field will do well to re-explore basic concepts with Dr. Glad.

FRANKLIN G. EBAUGH, M.D.,
Denver, Col.

NEUROPHARMACOLOGY. Edited by *Harold A. Abramson, M.D.* (New York City: Josiah Macy, Jr. Foundation, 1959, pp. 285. \$5.00.)

This is the transcript of the 4 discussions of the Fourth Josiah Macy Conference on Neuropharmacology held in September 1957. The verbatim style permits the reader to see the questions and doubts which arose in the mind of each participant but also records many sentences unfinished when someone interrupted, and deviations from the main topic. Considerable discussion is devoted to technical details of interest primarily to those attempting similar studies. Although there is no summary or conclusion and although one must read the entire text carefully to extract their ideas, these are quite valuable in furthering one's understanding of the biochemistry behind the actions of many psychopharmacologic products. Two short discussions deal with the effects of respiratory inhibitors upon Siamese fighting fish and the reactions of monkeys to electrical stimulation of various areas of the brain. The longer discussions deal with taraxein and its clinical effects and with the relationship between the chemical structure and physiologic action of various phenalkylamines and mescaline.

Taraxein is the name given by Heath to a labile substance found in the sera of schizophrenic patients which induce schizophrenic symptoms in normal individuals if administered rapidly by vein. Taraxein from a catatonic patient may induce paranoid symptoms as often as catatonic ones; which symptoms will appear in a given individual could not be predicted despite previous personality studies by as many as four psychiatrists. A spike discharge in the limbic areas was said to be constantly present in schizophrenics and "to accurately reflect the intensity of psychotic behavior." Taraxein was postulated to produce this action by altering the blood-brain barrier to permit normally occurring metabolites to gain entry into the brain cells resulting in both disordered electrical and psychic function. This postulate was not generally accepted and others had not been able to produce any effects by injections of taraxein. This most

interesting step in the search for a biochemical explanation of schizophrenia was left an open question pending further study.

Ceruloplasmin was mentioned frequently in both this discussion and in the last one as being involved in some fashion in mental disease. Its blood level is increased in any acute emotional state but is normal in chronic schizophrenics; it is increased by certain drugs but decreased by close analogues. Heath suggested it might act by metabolizing the excessive amines entering cells following alteration of membrane permeability (by taraxein) and reported some success in removing schizophrenic symptoms by its intravenous use. All agreed it acts as a phenol or catechol oxidase rather than attacking the C-N linkage as do the mono-amine oxidases but beyond that there was no general agreement.

The relations between the chemical structure and physiologic action of mescaline and phenalkylamines was discussed in great detail especially in relation to mono-amine oxidase. When this enzyme was inhibited, the metabolism shifted to an alternate pathway producing different degradation products which might induce alterations in physiologic and psychic responses. It is possible that the fact that a drug may act upon the peripheral nervous system to one degree and upon the central system to a different degree may be the result of the original drug or one metabolite acting at one site whereas another metabolite is active at the second site due to selectivity of the cells. Mullins theory is presented in which excitability of neurones is altered by changes in cell membrane permeability which will alter the passive flow of ions through the membrane and also the rate at which the cell pumps out excessive sodium. The drug molecule which most closely complements in size and spatial configuration the surface pattern of the cell will have the greatest potency. Small molecules fit crudely into many spaces and result in a very general action. Large molecules will find only few cells with the proper complementary surface configuration but will fit these most

accurately and will therefore be quite specific and selective in their action.

ROBERT R. SCHOPBACH, M.D.,
Henry Ford Hospital, Detroit.

ANATOMY: A REGIONAL STUDY OF HUMAN STRUCTURE. By Ernest Gardner, Donald F. Gray, and Ronan O'Rahilly. (Philadelphia: W. B. Saunders, pp. 999. \$15.00.)

This is a book on Gross Anatomy. It is directed to undergraduate medical and dental students, to provide information on living anatomy, and, by citation of relevant references, to meet the needs of the more advanced student and the postgraduate worker.

Introductory remarks include high lights on the History of Anatomy and guidance to anatomical literature and periodicals. Then come a hundred-odd pages on General Anatomy where consideration is given to the systems, to development and growth, and to radiological anatomy. Regional Anatomy occupies the following 845 pages; neuroanatomy, being a specialized field, is largely omitted. The concluding pages consists of an ample glossary of eponymous terms and a good index.

The illustrations, all in black and white, are numerous. In large measure they have been borrowed and re-drawn from contemporary sources and duly acknowledged. Some, perhaps, are rather bold and rugged, and some would have been more effective if it had not been necessary to reduce them to fit the available space—but, they fulfil their intended purpose. There are 64 good radiographic plates.

To write concisely both for the novice and for the research worker is a problem which the authors have largely overcome: in part by the use of large and small types, and in part by the profuse use of footnotes. The footnotes include derivations of words, definitions of terms, comments, documentary authority for statements in the text, and references to recent articles and to wider reading. Therein the book excels.

J. C. B. GRANT, M.D.,
University of Toronto.

DIAGNOSTIC AND DEMOGRAPHIC CHARACTERISTICS OF
PATIENTS SEEN IN OUTPATIENT PSYCHIATRIC CLINICS FOR
AN ENTIRE STATE (MARYLAND) : IMPLICATIONS FOR THE
PSYCHIATRIST AND THE MENTAL HEALTH PROGRAM
PLANNER¹

ANITA K. BAHN, Sc.D.,² CAROLINE A. CHANDLER, M.D.,³
AND LEON EISENBERG, M.D., F.A.P.A.⁴

This paper⁵ presents some of the findings of the first comprehensive study on the characteristics of psychiatric clinic outpatients of an entire State. Data were collected on the age, sex, color, place of residence, and mental disorder of every Maryland resident seen in a mental health clinic in the State or in nearby areas serving residents of the State during the year ending June 30, 1959. A mental health clinic was defined as "an administratively distinct psychiatric service for outpatients where a psychiatrist is in attendance at regularly scheduled hours and takes the medical responsibility for all the patients." It is our intention to demonstrate the usefulness to the psychiatrist, mental health program planner, sociologist and epidemiologist of such data obtained for an entire geographic area and therefore referable to a population base for computation of admission and termination rates.

The first point we wish to emphasize is that our data are not a description of the distribution of mental disorders in various population groups but rather of those receiving defined psychiatric services. The availability of various psychiatric facilities

and supporting services, clinic policies, cultural attitudes toward seeking and accepting psychiatric help, sophistication in recognizing psychiatric symptomatology, and community resources for case finding—all are selective factors determining who comes to clinics. As a result, the relation of the clinic population to the total mentally ill population is not known. For example, disturbed individuals seen by private psychiatrists, the Special Services Division of the Baltimore City Board of Education, probation services of the juvenile court, and social agencies are excluded. It has been estimated by various studies (1-3) that 10% or more of the non-institutionalized population are suffering from psychiatric disorders. Our figures, which indicate that less than one-half of 1% of the population are seen in a psychiatric clinic in a year, point to a large discrepancy between the total number who may be mentally ill and the number who are receiving outpatient services (4).

DEMOGRAPHIC CHARACTERISTICS

Table 1 compares the Maryland clinic admission rates for children and adults by place of residence and with national estimates. Rates adjusted for differences in the age distribution by place of residence were also computed. This adjustment modifies the figures in Table 1 slightly but does not affect the direction of the differences. Also we have estimated that rates based on number of individuals rather than on number of admissions would be approximately 5% lower for all groups.

In the more rural counties, clinic services are primarily for children while services for adults receive less emphasis. The relatively high rate for children in these counties reflects the use of the mental health clinic for

⁴ Associate Professor of Psychiatry, The Johns Hopkins University, Baltimore, Md.

⁵ This paper presents part of the findings of a methodological study of psychiatric clinic outpatients conducted by Dr. Bahn for the National Institute of Mental Health, Maryland State Department of Health, and the Johns Hopkins University School of Hygiene and Public Health. A monograph presenting detailed findings is in preparation.

TABLE 1

Admission Rates to Outpatient Psychiatric Clinics per 100,000 Population, by Major Age Group and Place of Residence: Maryland Residents, July 1, 1958 to June 30, 1959, and Estimated United States Total 1955

PLACE OF RESIDENCE	TOTAL	PATIENTS	PATIENTS
		UNDER 18 YEARS OF AGE	18 YEARS OF AGE AND OVER
Total Mary- land, 1958-59	285	292	280
Baltimore City	405	266	473
Metropolitan counties	220	258	197
Nonmetropolitan counties	230	386	141
United States (estimate) *			
1955	164	248	120

* Based on Bahn, A. K. and Norman, V. B.: First National Report on Patients of Mental Health Clinics, Public Health Rep. 74: 943-956, November 1959.

school psychological services and as a case-work and court diagnostic facility because of the lack of other community resources. If the special school services in Baltimore City were included in our statistics, the clinic admission rate for Baltimore City children would be more than tripled. The clinic data on rates of admission therefore indicate that where school systems lack testing facilities and where ancillary agency services are minimal, mental hygiene clinics tend to be dominated by service demands for psychological testing of children and social services. The uniformity, however, with which all clinics report long waiting lists for treatment of children indicates a marked inadequacy of services in all geographic areas.

The decrease in adult psychiatric rates from the more to the less urbanized area demonstrated in Table 1 for outpatients is similar to earlier findings which indicate that highest rates of hospitalization for schizophrenia occur in areas of high population mobility and density (5-7). The extent to which this gradient reflects differences in available services or differences in ecology (and in turn, ecological factors may represent cause or effect) is not known. There can be little doubt, however, that it reflects in part a deficiency of services for adults in the rural counties. Medical school and state mental hospital clinics are located in the large urban centers and are therefore rela-

tively inaccessible to rural residents. In order to improve services to the rural post-hospitalized patient, a system of referrals from state mental hospitals to county mental hygiene clinics and health departments is now being initiated.

Within Baltimore City, rates for nonwhites for some age groups in early adulthood are almost twice as high as those for whites (Figure 1), this large difference by color paralleling the rates of first admission to the state mental hospitals of Maryland (8), Ohio (9), and New York (10). Our findings are contrary, however, to those of the Baltimore Chronic Illness Survey (1) of a sample of the general population. The authors cite examination by white clinicians, differences in age distribution, and selective factors of hospitalization, as possible reasons for the low prevalence of certain mental disorders found for nonwhites. Differences in the methods of the two studies must also be considered: in the Baltimore Survey a sample of the general population was examined by internists whereas the present study is based upon people with psychiatric complaints who presented themselves at a clinic. Our data, indicating differences between whites and nonwhites, emphasize the need to explore the relation of such factors as socioeconomic level and differential migration (into and out of the city) to psychiatric illnesses, as well as the need to investigate differential utilization of facilities by whites and nonwhites.

Another significant finding is that clinic admission and termination rates are con-

FIGURE 1

ADMISSION RATES TO OUTPATIENT PSYCHIATRIC CLINICS, BALTIMORE CITY RESIDENTS BY AGE, COLOR AND SEX, JULY 1, 1958 TO JUNE 30, 1959

siderably higher for boys than girls. This finding has been observed in national statistics (11). We note here, in addition, the sex differential by diagnostic category—higher rates are observed for personality disorders, adjustment reactions, brain syndromes, and mental deficiency (Table 2). More boys than girls are admitted to nearly every clinic reporting to the study. In addition, more boys than girls are referred by almost every type of community agency. These data may reflect different and more obtrusive behavior deviations in males resulting in greater community intolerance, or more parental concern for boys; however, the higher morbidity rate among male children is well documented in other handicapping conditions also (12), and mortality in utero is higher for males (13). This suggests the need for intensive research into possible causes of these differences.

Interestingly, by about age 30, white female rates are as high as male and thereafter they are not dissimilar (Figure 2); among nonwhites, rates are higher for females than males at older ages (see Figure 1). First admission rates to mental hospitals, however, including private and public hospital data, and estimates for Veterans Administration hospitals, are somewhat higher for males than females (14).

Children under 5 and adults 65 years and over have the lowest rates of admission to clinics; high rates for school children are followed by a decline in late adolescence, a secondary rise at ages 30 to 40 years, fol-

FIGURE 2

lowed by another decline. Low rates for children under 5 years may be the result of a low prevalence of disorders, difficulty in detecting pathology, or reluctance to refer young children for psychiatric help. This is an area in which further knowledge is needed for control of mental illness. The data suggest, however, that case finding should be intensified. A pilot project in early case finding among preschool children has been initiated in well-baby clinics in Maryland. Infants and preschool children showing deviations in development and behavior are being referred for psychological evaluation.

The decline in clinic admissions at the end of adolescence appears to reflect the withdrawal of the school as the principal referral agent. Possibly, also, this is a period

TABLE 2

Termination Rates from Outpatient Psychiatric Clinics per 100,000 Population: Maryland Residents under 18
Years of Age, by Color and Sex, and by Mental Disorder, July 1, 1958 to June 30, 1959

MENTAL DISORDER	TOTAL	WHITE		NONWHITE	
		MALE	FEMALE	MALE	FEMALE
Total	269.2	366.1	189.0	285.1	159.9
Brain syndromes	38.4	43.4	27.1	68.0	34.6
Mental deficiency	44.3	52.1	36.9	57.8	27.5
Psychotic disorders	12.5	15.5	7.2	16.2	17.3
Psychophysiologic autonomic and visceral disorders	4.6	5.3	4.1	4.1	4.1
Psychoneurotic disorders	26.2	29.7	25.9	15.2	22.4
Personality disorders	57.9	95.3	29.5	55.8	14.3
Transient situational personality disorders	64.7	95.1	45.3	44.6	31.6
Without mental disorder	10.9	16.5	6.2	11.2	6.1
Not stated	9.8	13.3	7.4	12.2	2.0

of relatively low stress, coming after a period of academic demands and prior to the onset of family responsibilities. The marked change in rate of referral at the point that school attendance diminishes, nevertheless, emphasizes the importance of the school as a case finding agency for preventive psychiatry.

The increase in admission rates at ages 25-35 for white females and 30-40 for white males suggests areas for sociological investigation. For example, preliminary findings indicate that these ages coincide with the peak age of divorce after two or more marriages (15). Studies by Clausen(16) indicate the disruption of the marital relationship antecedent to hospitalization for mental illness, and those by Locke, *et. al.*(9), that rates of admission to public mental hospitals are highest for the separated and divorced. Information on the differential risk of admission to clinics by marital status is being planned for 1960 when denominator (census) data will be available.

The general decline in the clinic population past the age of 40 cannot be construed as an indication of diminishing mental pathology with age since it is accompanied by an increase in the rate of admission to inpatient care(11). The advent of new treatment methods, the declining resident mental hospital population(17, 18), and the growth of clinic services(19) can be expected to alter the present high ratio of inpatients to outpatients at these ages. The particularly low rates of admission to clinics for those 65 years and over concomitant with high rates of inpatient admissions, suggest that mental health clinics are not assuming a sufficiently important role in the care of geriatric patients. It is possible that intervention by a mental hygiene clinic could reduce the hospitalization rate for this group.

MENTAL DISORDERS AND SYMPTOMS

An important methodological contribution of this study, we believe, is that an impression of mental disorder was requested if a formal diagnosis could not be recorded. Clinic cooperation with this reporting procedure reduced the percentage of clinic patients, particularly children, with psychiatric classification not stated, from the national

average of 22%(11) to a low of 2% in the present study. The reporting and coding process permits separate study of diagnoses and impressions. Twenty-two percent of the children's classifications and 4% of the adults' classifications were impressions (Table 3). The proportion of children's cases reported as impressions is highest for mental deficiency and lowest for psychotic disorders. In this paper, impressions have been included with diagnoses in the rate computations in order to describe the patients as completely as possible. Data were tabulated on the broad and detailed categories of mental disorders, on severity of mental deficiency, and on selected symptom syndromes, to test the usefulness of the detailed diagnostic codes of the Diagnostic and Statistical Manual of the American Psychiatric Association(20). Only highlights of the findings are presented here.

We might look first at the age trend in the rates for each major category of mental disorder. Since mental disorder is reported only on termination of clinic services, the rates represent the number of clinic terminations per 100,000 population. As reported by clinics, the age curve for brain syndromes (Figure 3) tends to show three peaks, reflecting several different types of disease entities. Brain syndromes associated with prenatal and paranatal factors such as congenital cranial anomaly, mongolism, birth trauma, convulsive disorder, and unknown organic etiologies peak at early ages and generally continue at about the same level through age 15 years. Only convulsive disorder and other brain trauma do not decline rapidly thereafter. Except for white females,

TABLE 3

Percent of Psychiatric Classifications Reported as Impressions, by Psychiatric Classification and Major Age Group: Maryland Resident Terminations from Outpatient Psychiatric Clinics, July 1, 1958 to June 30, 1959

PSYCHIATRIC CLASSIFICATION	PATIENTS UNDER 18 YEARS OF AGE		PATIENTS 18 YEARS OF AGE AND OVER	
	NUMBER OF CASES	PERCENT REPORTED AS IMPRESSIONS	NUMBER OF CASES	PERCENT REPORTED AS IMPRESSIONS
Total patients with a psychiatric classification	2,728	21.7	4,509	4.0
Brain syndromes	404	11.5	424	2.8
Mental deficiency	466	36.1	127	7.9
Psychotic disorders	131	5.3	1,521	1.6
Psychophysiologic autonomic and visceral disorders	48	8.3	83	1.2
Psychoneurotic disorders	275	9.5	1,314	2.6
Personality disorders	609	21.3	888	9.5
Transient situational personality disorders	680	18.2	71	19.7
Without mental disorder	115	40.0	81	2.5

acute and chronic brain syndromes associated with alcohol intoxication are the principal components of the rates between the ages 25 to 64 years. In late adult life, brain syndromes associated with cerebral arteriosclerosis and senile or presenile brain disease are predominant; although based on small numbers of cases the higher non-white than white rates parallel the racial difference in the death rate from cerebrovascular accidents(21).

Mental deficiency without demonstrated organic cause is diagnosed in clinics primarily at school ages (5-14 years). At these ages it is more frequently reported than brain syndrome with mental deficiency (Table 4). The distinction between idiopathic and organic mental deficiency, however, is dependent almost entirely on the adequacy of diagnostic procedures and med-

ical history. Children seen by a psychiatrist in our study are more likely to be classified with a brain syndrome than children seen only by a clinical psychologist. It is possible that this difference represents case selection rather than variation in case evaluation by profession. However, it is our belief that rates for organic mental deficiency are understated primarily because complete diagnostic service is frequently not available to the mentally deficient child.

The relatively high clinic rate for brain syndrome and other mental retardation combined noted for young children support the assertion that primary prevention of mental illness should begin with high quality prenatal and early natal care(22-24).

Psychotic disorders are rare below the age of 5; the rate rises exponentially in early adolescence (Figure 4) doubling in each

TABLE 4

Termination Rates from Outpatient Psychiatric Clinics per 100,000 Population: Maryland Residents under 20 Years of Age with Symptom of Mental Deficiency, by Mental Disorder and Age, July 1, 1958 to June 30, 1959

MENTAL DISORDER	TOTAL	AGE GROUP			
		0-4 YEARS	5-9 YEARS	10-14 YEARS	15-19 YEARS
Total rate for symptom of mental deficiency	62.8	42.1	89.5	76.4	41.0
Mental deficiency (idiopathic or familial)	43.1	17.4	65.0	59.1	35.3
Chronic brain syndrome with mental deficiency	19.7	24.8	24.4	17.3	5.7

FIGURE 4

subsequent 5-year age group to young adulthood and then begins to decline. The age curve for females is of the same general shape as that for males, but tends to be "displaced" about 5 to 10 years later on the age scale. This earlier peak in the male psychotic disorder rate has been noted in hospital studies (6, 25).

The psychoneurotic disorder rate rises somewhat earlier; for males the increment slackens in late adolescence so that adult female rates exceed male rates particularly among nonwhites. These disorders peak in early adulthood.

Adult psychotic disorder rates are almost twice as high for nonwhites as for whites (Table 5). For nonwhite females, psychoneurotic disorder rates are also relatively high. The fact that nonwhite male rates

markedly exceed white male rates only for psychotic disorders raises interesting questions: is there selection in the kinds of referrals made to clinics, different diagnostic interpretations for each racial group, or are these real population differences in the relative frequency of various psychiatric illnesses?

As a group, personality disorders show the greatest difference by sex (Figure 5). In general during childhood, male rates are about three times as high as those for females and in adulthood they are about twice as high with some tendency for the female rate to peak at a later age than for males. Personality disorder rates generally decline by the age of 20 or 25 but some increase occurs around age 40 for whites due to alcoholism (addiction). (It is noteworthy that only 11 outpatients with drug addiction were reported.) The change in rates for personality disorders, with age, are provocative. What happens in adult years to individuals reported with personality disorders at younger ages? Do these persons appear instead in other "problem populations" such as in welfare or agency case-loads? Have the disorders changed to some other type such as psychotic disorders, or are individuals with personality disorders "immature" persons who eventually mature as suggested by studies of Glueck on criminals (26)?

The most striking feature about transient situational personality disorders (adjustment

reactions) is their considerable numeric importance in childhood and abrupt decline at 18 years (Figure 6). Since there is no similar marked decline in other disorders, the phenomenon may be that referred to earlier—the sharp drop in school referrals—coupled with removal of relatively healthy young males from the general population by the armed forces. Another factor, we believe, is that many clinicians are reluctant in their diagnoses of children to consider the pathology as other than transient. From examination of clinic records we have noted cases diagnosed under the classification of “transient situational personality disorder” where the disturbance was neither transient nor situational but rather severe and prolonged. In a study of 80 pediatric outpatients of a psychiatric clinic, for example, all were found to have had symptomatology for at least 6 months, and half for at least 2 years (27). In addition, a serious deficiency in the nomenclature is the lack of a detailed classi-

FIGURE 6

fication within this rubric (adjustment reactions) which is quantitatively so important for child patients.

Psychophysiologic autonomic and visceral disorders constitute a numerically unimportant category (about 2%) among clinic patients, an interesting contrast to the findings of the Baltimore Chronic Illness Survey of a sample of the general population(1). In the latter study, a third of all psychiatric cases diagnosed by internists were classified with this disorder. Either this reflects a difference between the types of diagnoses made by psychiatrists and by internists, or, as we are inclined to believe, a relatively small proportion of persons with psychosomatic illnesses are referred to psychiatric clinics.

In addition to mental retardation discussed earlier, the prevalence of certain other manifestations of mental illness are of interest irrespective of psychiatric classification. Clinics were requested to report the symptom of “excessive drinking” in order to provide an estimate of the extent of this problem among the patient population. Patients with brain syndromes associated with alcohol intoxication or with the disorder of alcoholism (addiction) represent less than half of the adults 20 years of age and over reported as problem drinkers (Table 6). A total of 25% of male patients and 9% of female patients are reported with this symptom. These are minimum estimates since for another 20% of males and 10% of females this information is not available. Information on problem drinking is an aid not only in individual prognosis, but also in ecological studies on alcoholism, and in the planning of alcoholism control programs. We recommend, therefore, that this symptom be reported routinely.

In concluding this brief psychiatric description of clinic patients in Maryland, we wish to urge both: 1. Continued study to improve the standard psychiatric classification as we progress in knowledge of etiology and psychopathology, and 2. Intensive field studies to improve reliability and comparability in the use of current classifications. Although there are at present some deficiencies in both areas, as with other illnesses, progress can be made only by the persistent attempt to classify and count separate dis-

TABLE 6

Terminations from Outpatient Psychiatric Clinics: Maryland Residents 20 Years of Age and Over with Problem Drinking, by Sex, July 1, 1958 to June 30, 1959

ease entities. Although symptoms or manifestations of a disease are useful, the reporting of symptoms alone cannot advance knowledge without clinical synthesis of the symptoms in terms of etiology and pathology.

DISCUSSION

In this paper we have presented some of the principal findings with respect to the demographic and psychiatric characteristics of the residents of a state who are outpatients of mental health clinics. These data, when related to a population base, point to large differences in the differential risk of clinic admission by age, sex, race, and place of residence. It would be of interest to compare these data with other health and welfare data in order to detect significant relationships.

Fact gathering on demographic and diagnostic characteristics of patients is the first step in reviewing a mental hygiene program in order to plan for comprehensive services. It enables one to specify who is being served and in what way. Only then is it possible to determine whether the actual pattern of service corresponds to an optimal plan based upon best available public health information(28).

We wish to encourage clinic studies in other geographic areas with large urban-rural and white-nonwhite populations for comparison with our findings. With the growing trend toward psychiatric treatment in the community as contrasted with treatment in the hospital, records from outpatient psychiatric facilities will become increasingly important in the study of persons who are referred to or seek psychiatric care.

The combined inpatient-outpatient population is a less-selected portion of the total

mentally ill than either group alone. In addition, a serious flaw in the present study is the lack of follow-up information relating to the subsequent psychiatric experiences of patients. The fact that about a fifth of the patients are readmissions to the same clinic indicates that we are dealing with a group subject to recurrence of illness.

A cumulative psychiatric case register file is needed, therefore, to obtain a more complete picture of diagnosed mental illness, and to follow individuals longitudinally through these facilities to answer such questions as: What is the unduplicated count of individuals by age, sex, color, and diagnosis, who are admitted to, terminated from, or under the care of a psychiatric facility within the year? What proportion of individuals diagnosed for the first time in a psychiatric clinic are subsequently admitted to a psychiatric hospital within a specified time after clinic discharge? What is the subsequent psychiatric history of an individual following first significant release from a mental hospital? Is the number and composition of the psychiatric population seen in psychiatric facilities fairly constant from year to year, or are there substantial yearly increments and decrements?

It is our immediate plan in Maryland to set up a coordinated research file on the inpatient and outpatient psychiatric population(29) to answer the above questions, to provide minimum estimates of incidence and prevalence, to aid in the study of the results of psychiatric care, and to observe changes in an individual's diagnosis over time, not only as an aid in determining diagnostic reliability, but also to provide further information on the natural history of mental disorders. The feasibility of augmenting this research file with data from private psychia-

trists and from the non-psychiatric counseling center will be explored.

SUMMARY

This study demonstrates the feasibility and utility of the routine collection of diagnostic and demographic data from all psychiatric outpatient clinics serving residents of a defined geographic area. These data added to existing mental hospital figures and supplemented by reports from private practicing psychiatrists and community agencies not under a psychiatrist's direction will provide a more complete identification of the community's mental health problems, an important step toward the ecology of mental illness.

DISCUSSION

ADDISON M. DUVAL, M.D. (Jefferson City, Mo.).—As a mental health program planner, I am very interested in using every available aid which may be helpful in our difficult assignment. I feel the authors of this report have

presented us with a specific additional method which will help to better identify the community's mental health needs.

In so stating, we should not be lulled into any sense of security about our total program, for this is but one aspect of the difficult estimate of psychiatric need which plagues the state program planner. Many additional yardsticks have been suggested, but none has been found to be entirely reliable. We have found that the use of mental health facilities in a state may be measured by the actual need for such facilities by mentally sick patients, but having said this, one is faced with the practical problem that one community refuses to use the facilities for reasons which are not even known to a second community. Such variant usability of the facilities may be based on prejudice, misinformation, financial ability or even religious antipathy for the hospital superintendent. Such things as the reputation of the hospital, its role and image in the community, and the attitude of the local press are also important.

There is reason to believe that there is little variation in the rate of psychosis from state to state. Yet the admission rate to state hospitals across America varies very widely. Missouri has the lowest state hospital admission rate of all the states—about 56 per 100,000 population. Yet the people of the state are not aware that there may be more psychotics in the Missouri community than in a state with 4 times our admission rate to its state hospitals. We also do not have enough outpatient clinics to serve the psychotics who presumably must be in the Missouri population. The practical question

arises : where are these people and why don't they come to our attention ?

Recent information points to the fact that short-term state hospital stay—with or without specific therapy—seems to reduce the chronicity of illness in days, months and years. Maybe our low admission rate (which in Missouri is not clearly understood) is another indication that generally we tend to hospitalize too many psychotic patients routinely—that if we would postpone such hospitalization for a time, it might actually be avoided entirely !

I have no specific quarrels with the authors of this paper. Their method adds another assist to the most complex decisions which face the mental health program planner, and for each of these we are most grateful. I would add a brief postscript to emphasize that (a) improved precision of psychiatric diagnosis would make this study more valuable, (b) the great need for follow-up studies of the case material presented as mentioned by the authors, and (c) to underscore and agree with the author's report that schools without test services will swamp the clinic staff with requests for psychological testing—often not indicated. In the same situation the school teacher will often wish to refer the aggressive boy and overlook the schizophrenic girl.

In my experience this can be almost entirely eliminated through an in-service psychiatric educational program for the teacher who can be taught to accurately estimate the seriousness of emotional disorders of children in her classroom.

THE AMSTERDAM MUNICIPAL PSYCHIATRIC SERVICE : A PSYCHIATRIC-SOCIOLOGICAL REVIEW ¹

PAUL V. LEMKAU, M.D., AND GUIDO M. CROCETTI, B.Sc.²

The personal experiences on which this report is based were obtained in the course of two visits to the Amsterdam Service.³ In the first of these visits the psychiatrist author spent 10 days with the service, attending conferences, interviewing physicians and nurses, visiting facilities, and making patient visits with both physicians and nurses. The second visit was a part of a month-long study of a number of community psychiatric services, both rural and urban, in the Netherlands by two sociologists experienced in research on medical services. They spent two weeks with the Amsterdam service in the manner already described but, profiting by the prior experience of the psychiatrist, with a better planned series of observations and with more clearly defined questions to be investigated. They interviewed a sample of personnel drawn from all levels of the service as well as key individuals from related agencies. These interviews were semistructured in nature and the Dutch and German languages as well as English were used. Many were recorded on tape in order to permit a more leisurely and detailed analysis. These interviews were obtained as privileged and confidential communications and are here quoted directly only where the respondent has already indicated a similar view in publications or intended the quotation for public information. In some instances material is summarized. Misinterpretation under such circumstances is, of course, possible and such as occurs is the responsibility of the authors.

The Municipal Psychiatric Services of Amsterdam are comprehensive in scope. Their resources and services reach pre-school children, children of school age, de-

fectives, emotionally disturbed and handicapped persons, adult psychotics in the community and in the psychiatric wards of the general hospitals. The non-hospitalized (including psychopaths and police cases), the psychotic prior to hospitalization, during hospitalization and after hospitalization, and geriatric patients are included.

Other health, medical and welfare services in the community and general social agencies frequently work with the municipal mental hygiene services. These services are, on the whole, well integrated and interlocking. There has been, through the years, a certain amount of movement of personnel from one branch to another, and there are frequent conferences between the various agencies. A network of formal and informal interpersonal relationships make communication easy and rapid. Throughout our sample of interviews, with one exception, the same general ideology regarding the service and its effectiveness, and attitudes towards it, prevailed among all levels of personnel in all branches of the service, with of course, some difference in degree of elaboration. The one exception is that of a more psychodynamically oriented psychiatrist who was deeply concerned with the lack of provision for the neurotic patients and the relative absence of resources for intensive psychotherapy.

Only one part of this essentially integrated and comprehensive service will be discussed here, but it is important to bear in mind throughout the discussion that this one aspect is only part of an interlocking, mutually-sustaining system of which any part has access to the resources of all the other parts.

The particular aspects we wish to discuss are termed by the service itself, in the shorthand of bureaucratic jargon, "the post-care program, the pre-care program, and the emergency program." These are not three distinct entities. They share the same administrative staff, headquarters, and personnel.

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² The Johns Hopkins University, School of Hygiene and Public Health, Baltimore, Md.

³ Financed by two separate grants from the Milbank Memorial Fund which are gratefully acknowledged.

This discussion will not include the conventional indices of program evaluation such as physician-patient ratio, nurse case-load or the statistics of visits and of patient movement. The intention is, rather, to discuss the ideology and attitudes, the practices and theoretic rationale, which appear to have important significance for the practice and development of social psychiatry.

The first program to be established was that for patients following psychiatric hospitalization, the post-care program. This program was the point of origin of much of the present system.

The way in which this system developed is probably significant for subsequent evolution of the psychiatric services in Amsterdam. In the Netherlands each community pays a *per diem* (per capita cost) for each resident of that community cared for in a mental hospital. At the inception of the program there were about 3,000 Amsterdam residents in Provincial and voluntary mental hospitals. This population was increasing at about 100 per year. This was a substantial and growing burden on the community already strained to recover from its very considerable losses in the War. The municipal authorities put a simple question to the municipal psychiatrists: "Could this population be reduced, or its rate of increase slowed?" It is important to note two things about this initiative, its origin and its motives. It originated in lay authority. Its major motive was economic, "How can we reduce costs?" Dr. Querido, the founder of the service, Dr. Gravesteyn, the present head of the service, and Dr. Piebenga, chief inspector for the Netherlands Hospitals, are all in agreement that economy was the major motive for the request. As Dr. Piebenga put it, "Economy was the mid-wife at the birth of the new program."

This is not to say that humanitarian and professional motives were completely absent. Amsterdam has a long history of providing adequate care for its mentally ill. But one of the main reasons for asking for change was an easily understood, reality-centered question and the goals implied were universally considered desirable. Given this origin and these motives, it is almost predictable that any reasonable answer would receive respectful consideration. The

implications of this for community-based psychiatric program planning are obvious.

The response to the question was empirical and quantitative. Querido visited the mental hospitals, establishing contacts, reading histories and examining patients. We will not dwell on skillful handling of the complicated interpersonal processes that were involved in establishing mutually friendly contacts and working relationships with hospital personnel. Suffice to say that the painstaking efforts of those days still show their fruit in the persistence of easy, flexible, mutually cooperative relationships as a new generation of professional leadership takes over. It should also be noted that one of the stated motives for cooperation on the part of hospital administration was as reality-centered as the motivation of the community. Hospitals were markedly overcrowded and understaffed. Anything that would reduce the resident population in a reasonable and humane manner would increase hospital effectiveness and provide a higher level of professional satisfaction.

Querido established that 10 to 20% of the resident mental hospital population from Amsterdam was being retained in hospital after having achieved maximum potential benefits from their stay, simply because of lack of alternative facilities to which they could be discharged. Querido visualized these alternative facilities as consisting of first, limited medical supervision and, second, housing to provide an adequate place for the discharged patient to live.

The question of medical supervision was met by providing for a combination of "office" (visits to headquarters) and home visits. Much has been said about the institution of psychiatric home visits in Amsterdam, but at this point we only wish to note that it was functionally realistic. If one accepts responsibility for the supervision of a psychotic patient in the community, then it follows that the failure of that patient to appear for a scheduled appointment is a cause for concern and action rather than for rejection. Thus, in such a program, home visits are imperative whatever the reason for the patient's inability to appear at an outpatient clinic or office. At present every patient is seen at home at least once by a psychiatrist. This is usually a screening

visit for admission to the service. He then, at the daily staff conference, prescribes the frequency of visits by the nurse-social worker which average once every two weeks per patient. She in turn may request additional psychiatric home visits if she feels the patient requires them but is unable, or cannot be relied on, to come to the office.

Housing was a very real problem. In Amsterdam, housing has perennially been in short supply. The city had suffered relatively heavy war damage and has had during the post-war years an especially acute housing problem. In fact, it was not until July of 1959 that the number of new houses started in Amsterdam exceeded the number of new families formed in the same period.

One need hardly comment on the inability of the psychotic patient, especially when hospitalized, to compete successfully for such a hard-to-get commodity. Querido's solution was to have the psychiatric service compete for the psychotic. He sought housing for the psychotic patients returning from hospital and for their families. This was done, and to this day in the allocation of new housing, the post-hospitalized psychotic patient is considered.

The development of two facets of the program have thus far been traced, home visitation and housing. There is a third: employment. Many patients potentially available for discharge from psychiatric hospital were capable of work. For some, work could be found in the sheltered workshops and training schools. Querido determined to place other patients in the open labor market. For this, recourse was had to the state employment service.

Work appears to have a special place in the Dutch culture. It is an integral part of the concept of a normal way of life and Querido in his social psychiatry ascribes to it a therapeutic function as well.

In this connection note must be taken of the general employment situation in the Netherlands. For some time there has been a "tight" labor market, with as many or more job opportunities as there are applicants. It has been estimated that among one million inhabitants of Amsterdam there were on the average in 1959, only 2,000 people seeking work but unplaced. It would be difficult to match this situation in the

United States even at high levels of employment.

Initially, an employment counsellor was assigned to the mental hygiene service on a part-time basis. Later, as the service developed and expanded, the same employment counsellor was assigned full time. Although drawing his pay from the employment service he works as an integral part of the post-hospital service. In the interview with him he reported an interesting change in attitude having taken place as his employment conditions changed. During the period of his part-time assignment he reports feelings of frustration and hostility that occurred when he had placed an individual in a job and when that same person—as occurred in many if not most cases—showed up again because he had left his job for some reason he, the counsellor, thought trivial and irresponsible, requesting a new placement and armed with a note from the psychiatrist or nurse requesting such. He explains that he felt that either he was failing in his work or that the psychiatrist or nurse was being "put-upon" by the patient, that they were very gullible not to protest what he considered overusage of services. He came to realize that he was measuring his performance against that of his colleagues who were dealing with a different population. Later, with full time assignment to the service, with increasing contact with personnel of the service and with growing insight, he re-defined his task in terms of different and more therapeutically oriented standards. The objective he now defines is not permanent placement, but keeping the patient employed as frequently and as long as possible. This not only has tangible monetary returns and is understandable to the entire community, but is also, in this work-centered society, a highly approved goal. On the other hand, this also means a further involvement of the community in the problem of its mentally ill, not in some socially or geographically distant hospital, but "on the job."

We thus have three elements of the service: medical supervision, housing, and work.

For various reasons, this program, originally designed to facilitate the discharge of patients from hospital, was extended to

those patients in the community who were awaiting hospitalization. Some of these patients had been diagnosed as needing hospitalization. Others were picked up by the service in its effort to screen out admissions that were essentially social problems and that could be dealt with in the community. Still others were referrals from physicians and from the police. This was termed the "pre-care" service. Again the motivations from the extension were clear and communicable and were considered highly desirable on the part of the community.

In the working of this extended service it was found possible to retain many patients who would formerly have been hospitalized in the community, utilizing the same pattern of services as already existed in the "post-care program." The acceptance of these patients meant the assumption of a much greater degree of management responsibility for them. In the post-care program, responsibility is to some extent shared with hospital personnel. In the "pre-care" program the entire responsibility falls on the community psychiatrist. In reality the acceptance of the responsibility appears to have been inevitable. Mental hospitals were crowded. Admissions were often delayed from 10 days to 2 weeks and more. Someone had to assume responsibility for the patients when there simply was no place to hospitalize them. The willingness to assume this responsibility developed out of the success in handling similar psychotic breaks occurring in discharged patients. There was a growing feeling of confidence. "The striking thing," said one psychiatrist, "is not the number of undesirable effects of a psychotic break, but the number of times nothing happens at all." One is struck by what seems, in contrast to American practice, the matter-of-fact way in which the psychiatrist in the Amsterdam service—or perhaps we should say the psychiatrist who survives in the Amsterdam service—handles a psychotic episode in the environment of a tenement or crowded apartment.

There is a final program to be discussed: the emergency service. When responsibility for all psychiatric admissions and for cases awaiting admission was assumed, it was recognized that the service was a 24-hour responsibility, that psychiatric emergencies

had to be handled whenever and wherever they occurred. Staff was put on a 24-hour basis so that at any time of the day or night an emergency could be acted on. Interestingly enough all psychiatrists interviewed reported this seemingly onerous part of their duties as an interesting and rewarding one.

Calls are accepted from the police, from physicians in the community, and, under some circumstances, from relatives or neighbors. Since facilities for hospitalization are limited, in almost all cases the psychiatrist on emergency duty attempts a temporary solution, pending the application of the full resources of the service. In well over 70% of the cases the emergency call does *not* result in hospitalization in connection with the episode. In many cases the emergency call concerns a patient already known to the service. It is interesting to notice that through the years the utilization of the emergency service has declined significantly in spite of an increase in the population of Amsterdam. In 1954 there were 1,419 emergency calls. In 1956 there were 411. All psychiatrists interviewed reported in their own clinical experience a lessening of psychotic violence of the sort as to create a psychiatric emergency. Whether this reflects a greater accessibility of psychiatric service or other factors is not clear.

All of this leads to a conception—a theoretic rationale—of social therapy which is generally shared throughout the service. It should be emphasized that this is not a conception which includes the neurotic patient. The general consensus of psychiatric opinion among those working in the service is that the service provides a very unhealthy milieu for the neurotic because it encourages dependency and exploitation. This is, rather, a service designed for those who can exist in the community with a productive amount of social function only if given a certain degree of protection and shelter. The purpose of such a service, according to Querido, "Is to erect a buffer between society and the patient." Within the shadow of this buffer, the patients remain in the community.

There are three elements to this "social therapy." First, there is the acceptance of a long-term management responsibility. This management is directive in nature, concerns

itself with the infinite detail of daily life and frequently acts to protect the patient from the consequences of his own behavior. An illustration of this management is the case of an elderly couple where the wife was psychotic. They had been planning a vacation that was considered most desirable in that it provided the blind diabetic husband with an annual respite. The couple were, however, declining the vacation because they would not take their pet parakeet along and were unable to find someone to care for it. In a matter of seconds the situation was resolved by the nurse-social worker who undertook the responsibility for the parakeet. Needless to say, she also checked supplies of medication, inspected vacation plans, examined the budget and generally assured herself that the planned vacation was feasible.

All this is quite in contrast to our more restricted practice of simply assisting the patient to work out his own problems. The aim here is not cure, but the goal is realistic management in terms of community life. The problem of management was described by a psychiatrist not as one of seeing what the nature of the illness is but "as seeing what the patient does with his illness in the sphere of reality" and, if necessary, mitigating the consequences of his illness so that he can continue to function in the realm of "community reality."

The second element of this conception of social therapy follows logically from the first—direct manipulation of the patients' social environment in order to minimize the consequences of the illness. This is not simply to protect the patient from reality, but also to protect the surrounding group. A psychotic youth may be removed from a household, temporarily or permanently, in order to relieve the parents. Termination of employment in a given situation may be advised. In short, the living of the psychotic is channeled into those areas where there is the least social and emotional cost to himself and to his group. Complaints of neighbors and employers are listened to sympathetically and often acted upon. Repetitions of strained situations are not defined as failures but simply as symptomatic of

the need for further manipulation. Lest an erroneous impression be gathered from the discussion of these two elements, it should be emphasized that the average length of stay on the service is about two years. In spite of these dependency creating notions, many patients learn to shift for themselves after a period of time.

The third element of the social therapy may be termed an ideological one. It is perhaps best expressed in sociological terms. The concept of the social institution is central to sociology. The early sociologists, however, had a great deal of trouble distinguishing their concept of "institution" from the popular concept which was that of a physical structure of brick-and-mortar—the orphanage, the hospital, the jail. The concept that the *sociologists* were expressing was one of the "institution" as a set of social practices, routines, patterns of social behavior. According to McIver, an "institution" is a "form of social procedure," in other words, an accepted pattern of behavior. What seems to have happened in Amsterdam is that a pattern of social behavior has been created which provides, for a segment of the population of psychotics, most of the protection usually provided by the brick-and-mortar institution of the popular conception.

The implications of this social institution invite research investigation. A most pressing question concerns the cost, in psychological terms, to the community of maintaining psychotic individuals in close proximity to developing personalities.

What are the implications of the way in which the Amsterdam program grew and developed? It is tempting to generalize and say that programs of community psychiatry are always best built upon the expressed needs of the community. Popular motivations ought, then, always to be accepted and utilized. Under such circumstances, perhaps community involvement to the extent of commitment of necessary resources is more likely. Perhaps these statements are true. But more research is needed before these propositions can be fully accepted.

INTRA AND EXTRAMURAL COMMUNITY PSYCHIATRY¹

MAXWELL JONES, M.D.²

A therapeutic community(1) is distinctive among other comparable treatment centers in the way the institution's total resources, both staff and patients, are self-consciously pooled in furthering treatment. This implies, above all, a change in the usual status of patients. In collaboration with the staff, they now become active participants in the therapy of other patients and in other aspects of the overall hospital work, in contrast to their relatively more passive, recipient role in conventional treatment regimes.

The social structure of a therapeutic community is characteristically different from the more traditional hospital ward. The term implies that the whole community of staff and patients is involved at least partly in treatment and administration. The extent to which this is practicable or desirable will depend on many variables, including the attitude of the leader and the other staff, the type of patients being treated, the sanctions afforded by higher authority, *etc.* The emphasis on free communication in and between both staff and patient groups and on permissive attitudes which encourage free expression of feeling imply a democratic equalitarian, rather than a traditional hierarchical, social organisation.

Staff and patient roles and role relationships are the subject of frequent examination and discussion. This is devised to increase the effectiveness of roles and sharpen the community's perception of them. Thus, it may be felt that a nurse's role is clarified and rendered more effective if she ceases to wear a uniform. It may take many months of study and discussion to decide that, say, a student nurse requires, on an average, 4 months on a ward before she feels secure enough to discard her uniform. To share this discussion with the patients is to increase their awareness of the difficul-

ties of a nursing role and may modify their relationship to the nurses. The aim is to achieve sufficient role flexibility so that the role at any one time reflects the expectations of behavior of both staff and patients collectively.

The examination and clarification of roles inevitably sharpens the role prescription but may at the same time lead to some role blurring. This is not contradictory, as much depends on the nature of the role relationships. Thus, it may seem appropriate that nurses as well as social workers should visit patients' homes. The former might accompany patients on home visits to help in the rehabilitation process to the outside world. The social worker might visit the home with the patient's approval but not in his presence. Her visit might be mainly to try and engage the family members in treatment which would be complementary to the patient's treatment in hospital.

The overall culture in a ward or psychiatric unit represents the accumulation through time of the attitudes, beliefs and behaviour patterns, common to a large part of the unit. This is arrived at as a result of considerable inquiry into the nature of these attitudes, *etc.*, and an attempt is made to modify them to meet the treatment needs of the patients. In this context the term "therapeutic culture" is, sometimes perhaps, hopefully used. The tendency is for these cultural patterns to be most clearly established in the more stable and permanent members of the community, *i.e.*, the staff.

Examples of such attitudes contributing to a therapeutic culture or treatment ideology would be an emphasis on active rehabilitation, as against "custodialism" and segregation; "democratization" in contrast to the old hierarchies and formalities of status differentiation; "permissiveness" in contrast to the stereotyped patterns of communication and behaviour; and "communism" as opposed to highly specialised therapeutic roles often limited to the doctor.

Hospitalization is only one aspect of treatment, and it is necessary to consider

¹Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

²Commonwealth Visiting Professor in Psychiatry, Stanford University, Calif., now Director of Education and Research, Oregon State Hosp., Salem.

the extension of treatment into the outside community. The combined effect of physical treatments, including tranquilizers and social rehabilitation, has been to make many more psychotic patients well enough to return to at least a limited existence in the outside world. The degree of improvement in the remission rate in schizophrenia has not yet been fully assessed, but fairly comprehensive studies have been reported from both sides of the Atlantic. Brown(2) and his associates in London studying post-hospital adjustment in a group of 229 chronic patients found that 68% of these patients succeeded in remaining out of hospital for at least a year, and of these 66% were rated as showing either full or partial social adjustment. Successful outcome was associated with the patients' clinical state on discharge, with their subsequent employment, and with the social group to which they went: patients staying with siblings or in lodgings did better than those staying with parents, with wives, or in large hostels. Freeman and Simmons(3) in America studied psychotics discharged from hospitals and contrasted the outcome of those who returned to conjugal and to parental settings. They found that the wives have higher expectations of performance in relation to the recovered patient than do parents. The tendency to involve families in the treatment and management of their sick members in collaboration with psychiatrists is a current trend in all types of psychiatric illness. The day hospital is one example of this trend, and the much quoted experience at Worthing(4) in England was that during 1957 the anticipated admissions to the parent mental hospital at Graylingwell dropped by 56%, and in the following year by 62% compared with 1956. This means that many patients who in previous years would have presumably been admitted to hospital were now being cared for in the community on an outpatient day care basis.

One effect of this change is to put new kinds of stress on the community. The family are encouraged to keep "Grannie" at home and make do with psychiatric help as required. The general practitioner is more actively involved and by necessity is brought into much closer collaboration with the psychiatrist than previously. The local

health authorities have greater calls on their resources, and more extensive training in the psychiatric aspects of their work is becoming necessary for public health nurses and so on.

These changes have come about largely as a response to improved treatment methods in hospitals and a greater awareness of the needs of the patient in social rehabilitation. One could say that these changes have occurred largely within the past 10 years or even less. It is comparatively easy to change the culture of a hospital where the role of the doctor is preeminently that of a leader and the whole culture is or should be geared to therapy. This motivating force is a unifying factor to an extent that is impossible in the much more complex and extensive outside society. Patients have come to feel a new responsibility for their fellow patients and doctors have become interested in their patients as people, but have we any right to assume that the rapid change in the climate of opinion in hospitals will be matched by a correspondingly rapid change in opinion outside?

To start from the beginning, how well are we informed about public opinion in general towards mental illness? The National Opinion Research Center of the University of Chicago have carried out more than 3,500 interviews with a cross-section of American adults since 1950. Shirley Starr (5) reports that only 11% of the sample studied believe that a psychotic cannot get better again. On questions relating to recommending psychiatric facilities, the positive answers were generally better than 50%. When the respondent is asked what mental illness means to him, he generally distinguished between "nervous conditions" and "insanity" and included both as forms of mental illness. In effect, he agrees with the modern psychiatric distinction between psychoses and the personality disorders and includes both as forms of mental illness. In another context, however, when the respondent is not self-consciously giving a definition but is speaking spontaneously, he tends to slip into an identification of mental illness with psychosis only. He does not honor his earlier agreement that personality disorders are part of mental illness too.

Other studies have dealt with the prob-

lem of changing community attitudes towards mental health, but the results of such studies are conflicting (6, 7). It may be that we can, in time, achieve new skills in altering community attitudes towards mental illness, and here lies a whole area for future study. There is a possible analogy with the therapeutic community concept. In the latter, the nurses who once played a largely custodial role now, when personality factors and training permit, play an essentially therapeutic one. How far this pattern can repeat itself, now substituting family members for nurses and treating the patient in the home instead of in hospital, remains to be seen. In these two situations the psychiatrist should theoretically be equally competent. How far is this true in the current European or American scene? How competent is a psychiatrist or a social worker as currently trained to assess the nature and degree of disorganization within a family? To determine who really is the sick member or members? How willing is he either to change his role and operate in the patient's home milieu rather than in his office? The fact would seem to be that as yet there is no adequate training in social psychiatry.

It would seem that the idea of a mental hospital as such is becoming out-of-date. In Britain the new Mental Health Bill does away with the designated hospital and any hospital may now have psychiatric beds where patients may come and go without any formality whatsoever. In addition, commitment procedures which are now invoked in only 13.5% (8) of all admissions to mental hospitals will be still further simplified by requiring two medical certificates only and no legal involvement at all. However, review tribunals are available to any patient who may wish to dispute his commitment and the chairman of this tribunal will be a lawyer. Virtually all mental hospitals in Britain offer outpatient facilities to the areas which they serve,³ and psychiatric specialists make frequent domiciliary diagnostic visits to the patient in his home; 22,809 such visits were made in 1958. In progressive mental hospitals the medical staff may spend about half their time in

hospital and half their time in the extramural services. The hospital is already beginning to feel bypassed and nurses are asking for roles that are more community centered. The center of teaching, psychiatric assessment, and short term treatment is passing to the small diagnostic unit attached to the general hospital.⁴ The mental hospitals will probably tend to become long stay annexes and one is presented with the rather tragic anomaly that the very people who have given so much to the progressive aspects of British psychiatry may find themselves relegated to a relatively unimportant role. However, this is probably more a symptom of reaction to change than a reality, and the vitality that produced the change will probably achieve a solution, *e.g.*, the long stay annexes may well become something very different to even our present concept of a mental hospital. Given patients who as a group will, in most cases, be capable of only a marginal adjustment in outside society, if at all, then what sort of social organization should be evolved to give them the optimal social conditions compatible with their mental state? It is possible that something more like a village settlement than a hospital will emerge. Already several mental hospitals have demonstrated the feasibility of employing even disturbed and hallucinated schizophrenic patients on paid production work in a hospital factory doing contract work for outside firms (9, 10). Such a functional role has been shown to improve the social adjustment of such long stay patients and demonstrates that they are capable of working harmoniously with ordinary people (11). At Embreeville State Hospital in Pennsylvania and Mapperley Hospital in Nottingham, England, some long stay patients look after their own wards. In Southern Nigeria, Doctor T. A. Lambo has found that the new mental hospital built by the British is feared by the local inhabitants who view a hospital as a place where people go to die. Not having had mental hospitals in the past, they were unaffected by the custodial excesses which we associate with mental hospitals in the West during the past hundred years. Taking the local village culture into

³ There are more than 500 psychiatric outpatient clinics for adults in England and Wales.

⁴ There are some 43 psychiatric clinics attached to general hospitals in England and Wales (1958).

account he felt that the patients would be happier and get better sooner if they lived in familiar surroundings. He found a village which was prepared to absorb mental patients and their families. This has proved to be so successful that two other village settlements have been started. This experience has much in common with the centuries-old family treatment program in Geel, Belgium. These various examples point the way to social organizations for the treatment of mental patients quite different to the mental hospital as we have conceived it in the past.

In brief, it seems that a social revolution has started in psychiatry, and no one can yet foretell where it will lead us. It seems certain that the mental hospital will change fundamentally. It will probably become much smaller or, as a compromise, the large hospital will break down into several smaller semi-autonomous units(12). The social structure of the future hospital may well change in the direction of more ordinary "village settlements" with their own factories, the maximum possible range of role playing opportunities, and a large degree of self determination. Along with this may well go a radical change in medical and staff roles generally. The center of gravity of psychiatric endeavor may well move from the state hospital to the small assessment teaching and treatment unit in the general hospital, with a concurrent development of much more active community services and greater involvement of the general practitioner and local social service agencies. Titmuss(13) has warned us against over

optimism regarding economy when home treatment is compared with hospital treatment. Nor do we know how communities will react to the role for which they are being cast by psychiatric theorists. We need to know much more about community attitudes to mental health and how, if possible, to modify these in ways favorable to the betterment of mental health(14).

A COMPARISON OF RESULTS OF CONTROLLED DRUG EVALUATIONS IN TWO STATE HOSPITALS

JACKSON A. SMITH, M.D.,¹ CARL GOULDMAN, M.D.,² AND
WALTER M. GYSIN, M.D.³

The need for an effective treatment for the chronically mentally ill continues; and it is fortunate that potentially beneficial compounds are becoming increasingly available. A method of rapidly determining which of these new compounds are of value and which should be discarded is also a continuing need. This report describes such a method of evaluation and a comparison to test the validity of the procedure followed.⁴

MINIMAL REQUIREMENTS IN DRUG EVALUATION STUDIES

If the changes observed during the course of a study are to be attributed to the compound being evaluated, certain significant variables must be considered, and insofar as is practical, controlled. These variables include the selection of a group homogeneous as to duration of hospitalization, characteristic behavior and age. The hospital environment that was in effect before the project was initiated should be continued with a minimal increase in attention, contact with new personnel or other interruption of the patient's previous routine.

In addition to these controls, a standardized method of reporting behavioral change is required. These reports should include detailed observations by trained staff as well as the daily impressions of the ward personnel.

The types of patients to be tested and the personnel available must be considered in selecting a method of reporting behavioral change. For instance, psychological tests which require the patients' participation and sustained interest are of little value in evaluating chronic patients. Involved

rating scales with complex instructions may be meaningless to the aide; and the validity of the data collected is hardly increased by the aide's marking his confusion with a 4 plus or a 1 plus.

Unfortunately, there are a great many more psychological tests available for measuring behavioral change than there are psychologists to administer them in most chronic mental hospitals. These psychologists who are available, are not always interested in repeatedly testing large groups of chronic patients.

Whatever system for recording behavioral change is evolved should include observations made by more than one individual at different periods during the day. Since if significant improvement or side effects occur, they should be sustained sufficiently to be obvious to more than one observer.

If groups homogeneous for the factors described are chosen and if a method of measuring improvement or side effects is used which is understandable to the available personnel and capable of reflecting significant change in behavior, then comparable results should be obtained in hospitals with similar patient populations.

The following is a report on the comparison of the results obtained using such a system(1).

METHOD

The following request for a drug study was sent to the psychiatric nurses in charge of the research units in two state hospitals:

Patient Group:

Number: 25 to 35

Duration of hospitalization: 1 year or over

Sex: Male and female

Age: 25 to 65

Diagnosis: Not important but patient should have history of disturbed behavior.

Length of study: 8 weeks

Evaluation: Detailed control evaluation; to be repeated at end of 4th week and 8th week. Weekly progress notes(2).

¹ Clinical Director, Illinois State Psychiatric Institute, Chicago, Ill.

² Director of Research, Hastings State Hospital, Hastings, Neb.

³ Clinical Director, Norfolk State Hospital, Norfolk, Neb.

⁴ This study was supported in part by a grant in aid by the Smith, Kline and French Company who also supplied the drugs.

Laboratory tests: Complete blood counts and urinalyses weekly.

Compounds to be tested: Stelazine (trifluoperazine) Vontil (N-N-dimethyl-10(3-(1-methyl-4-piperazinyl)-propyl) dimethylanesulfonate)

Side Effects Anticipated: Those seen with phenothiazine derivatives.

Dosage:

Vontil 1 mgm. for 4 weeks, orally

2 mgm. t.i.d. for 4 weeks, orally

Stelazine 2 mgm. t.i.d. for 4 weeks, orally

4 mgm. t.i.d. for 4 weeks, orally

The research staffs of the two hospitals were not aware that the compounds were being run simultaneously. The institutions were located in different areas in the state and there was no direct professional or administrative communication between the two. Figures 1 and 2 show the groups chosen in Hospitals A and B.

The groups were remarkably similar as to average age and duration of hospitalization. The most apparent difference was in the types of patient included; all the patients in Hospital A were diagnosed schizophrenia, while at Hospital B, 5 men-

tally deficient individuals, a chronic brain syndrome and one manic-depressive reaction were included.

MEASURE OF IMPROVEMENT

Indication of a consistent though slight increase in 2 or more of the following was taken as evidence of improvement in both hospitals:

Participation in activities

Socialization

Interest in personal appearance

Appropriate affect and speech

Attention span, alertness

"Feeling better" (patient's statement)

Friendliness

Cooperation

Attempt to communicate

Decrease in:

Agitation

Tension

Incontinence

Overt Hostility

FACTORS INDICATING SIDE EFFECTS

Leukopenia

Facial edema, skin rash

Tremor, loss of associated movements, muscular rigidity

Drooling, mask-like facies or dysphagia

Decrease in motor activity sufficient to interfere with participation in routine activities

Marked hypotension, syncope

Nausea and vomiting

Marked pallor

Increased agitation with depression and somatic complaints

FIGURE 1

HOSPITAL A

Patients: 35 Female: 19 Male: 16

RESULTS

	Drug	No. of Pts.	No. Improved	No. Side Effects
Hosp. A	Vontil	17	5	7
	Stelazine	18	4	10
	Totals	35	9 (25%)	17 (49%)
Hosp. B	Vontil	15	3	5
	Stelazine	14	2	3
	Totals	29	5 (17%)	8 (28%)

DISCUSSION

Hospital A reported improvements occurring in 25% of their group and Hospital B noted improvement in 17%. This discrepancy is attributed to differences in the observations the evaluators considered

significant and in the patients in the groups being tested. Hospital A also reported a higher incidence of side effects.

In view of the proximate results of these trials, it appears that research nurses and ward personnel can observe and record behavioral change in chronic patients with sufficient reliability to carry out drug evaluation studies. It is also apparent that although the two drugs tested are surely an aid in controlling the disturbed chronic

patient, the need for more definitive treatment for such groups will require continuing evaluation programs.

ALTERNATING PSYCHOSES IN TWINS : REPORT OF 4 CASES¹

E. GARDNER JACOBS, M.D.,² AND ALVIN M. MESNIKOFF, M.D.³

Twins have a peculiar fascination for children and most adults. Burlingham(1) has pointed out that the fantasy of having a twin occurs frequently in childhood. Normal and abnormal aspects of personality development in twins have received widespread interest, partly because twin studies are believed to provide opportunity for separating hereditary and environmental influences on the development of an individual.

Large series of twins with psychotic manifestations have been studied by Kallman (2) and Slater(3) and in these the influence of genetic factors has been emphasized. Psychological patterns have been discussed in smaller numbers of twins by Burlingham (1) and others(4, 5, 6, 7). The successive occurrence of psychoses in twins within a short period of time has been reported(1, 4, 8) but reasons for this have not been advanced.

We were impressed by the interaction between the twins in each pair of our series and have attempted to determine how this interaction has influenced their emotional status and symptomatology.⁴

Four pairs of twins in which a psychotic reaction in one appeared to precipitate a similar reaction in the other were followed. Three pairs were identical, one fraternal. Psychiatric interviews, psychological tests, hospital records, and follow-up reports were used to elucidate this "contagion" of illness. Although the term alternating psychosis refers to a temporal sequence of events, the

details of the sequence varied in the 4 cases (Figure 1). The interval between the second twin's learning of the psychotic reaction in the first and the onset of psychosis in the second varied from one day to two months.

Case A.—Helen and Jane were 30-year-old identical twins admitted to the hospital in 1959 with paranoid schizophrenic reactions.

In 1957 Helen's husband began his own business and incurred a loss of income. Although Helen initially opposed this venture, she later appeared to accept the reasons given by her husband for the change. She began, however, to show hypomanic behavior and developed fears of various diseases, mainly gynecological and cardiac. Curettage done in 1958 and again in 1959 showed no abnormalities. In July 1959 she entered a psychiatric hospital for the first time because of marked somatic preoccupation and grandiosity. In the hospital she improved rapidly and was discharged in 3 weeks.

Jane reacted to Helen's hospitalization with apprehension concerning her own sanity and the health of her children. She began accusing her husband of infidelity and robbery and believed she was being poisoned first by her own and then by Helen's husband. She also had a number of somatic symptoms similar to her sister's. Although Jane had always been the more independent and popular while they were growing up, she turned to Helen for support after Helen's return from the hospital. Helen resented this dependency and told Jane of the jealousy she had always felt toward her in the past. Jane responded with anxiety and was admitted to another hospital. She arranged, however, to be transferred to the hospital Helen had recently left and to have the same psychiatrist.

Following Jane's hospitalization, her husband and children went to Helen's home to live. A month later, however, they returned to their own home because of Helen's hostility toward them. After their departure Helen began to fear she was pregnant and became depressed. The day after Jane returned home Helen was readmitted to the hospital. In the hospital Helen talked openly of her anger toward her sister for the latter's dependence on her. With psychotherapy, she gradually

FIGURE 1

improved and was discharged in 3 months.

Of note in the early history is a lack of overt mental illness in the twins despite depression and paranoid thinking in the parents. Jane was voted the most popular girl in her high school class, did well academically, finished nursing school without difficulty, married, and had 4 children before the onset of her psychosis. Her sister, although more quiet and serious, had a similar life pattern. Of interest because of the observations of Leonard (6) is the reported fact that the father was unable to distinguish one from the other until they were adults.

Psychological tests at the hospital compared the two sisters. These tests showed that Helen, from a characterological and descriptive standpoint, used hysterical defenses more than Jane, displayed more free affect, and tended more toward loneliness and depression. Jane was more obsessive and phobic but also more mature and better integrated. She was more perceptive and reality-oriented. She showed greater attachment to Helen than did Helen to her.

During Helen's psychosis, Jane became apprehensive and guilty about her sister's fate. As her thinking became more paranoid and her ability to maintain her equilibrium less adequate, she became more dependent on Helen.

Helen, now feeling stronger and less afraid of her twin sister, expressed the jealous resentment she had long felt. She attempted to reduce and expiate her resulting guilt by caring for Jane's family. Her reaction formation in the form of doing for others was not adequate, however, to conceal and contain her anger, resulting from the dependency demands of Jane's family. She also seemed to be defending herself against a fantasied relationship with Jane's husband. Her anger became more overt than before Jane's psychosis. When Jane's family left her home, Helen responded with guilt and depression.

Case B.—Sarah and Ruby were 45-year-old identical twins. Ruby first became depressed in 1941 following Sarah's marriage and was given outpatient electroshock therapy. Following the birth of Sarah's only child in 1943, Ruby had a psychotic reaction, schizo-affective in type. This reaction led to her initial admission to a psychiatric hospital, where she received insulin coma treatment.

During the next two years Sarah was increasingly preoccupied with the care of her colicky child. She began to complain of a neighbor's attention to her husband, accused her husband of infidelity, and became depressed. She was admitted to a psychiatric hospital and received a course of electro-shock treatments.

In 1950, Sarah's husband had an accident at work resulting in the loss of a leg. She became depressed and paranoid, feeling that Ruby was influencing her son, turning him against her. She was again hospitalized. Ruby became depressed and two months later was herself admitted to another hospital in a depressed state. She had delusions of a religious nature. In 1952, following a brief extra-marital experience, Sarah again became depressed and attempted suicide with poison.

In 1957 Sarah repaid a loan that had been made by Ruby following the accident in 1950. Ruby believed that interest should have been offered and thereafter visited her sister less often than she had before. Sarah became obsessively preoccupied with religion and had some bizarre religious delusions.

When, subsequently, Sarah's husband gave large amounts of money to two sons by his first wife, she felt he was taking advantage of her and developed paranoid thinking. She was taken regularly by Ruby for outpatient psychiatric treatment. In 1959, because of the persistence of her symptoms, she was rehospitalized.

Concurrently, Ruby asked Sarah's psychiatrist if he would accept her as a patient. She began outpatient treatment with him and, after becoming increasingly more depressed, was admitted to the same hospital as her sister. Both sisters improved symptomatically with further ECT and were able to return home, each within two months.

Psychological tests indicated that Ruby was more assertive, aggressive, and obsessive than Sarah, who was more schizoid. Ruby showed deep-seated feelings of rejection and felt her sister had been preferred by their father. Both sisters fantasied that their husbands were unfaithful.

Ruby, normally the more independent and externally oriented of the twins, felt deprived when Sarah developed a family life apart from the twinship. Ruby's independence, like Jane's, appeared to be a pseudo-independence that served to conceal her hostile and jealous but dependent relationship to her twin. Sarah became depressed and paranoid when there was a change in her relationship to her husband. Twice, when Sarah became psychotic, there was a disturbance in Ruby's adaptation and she also became psychotic. Sarah's illness magically "confirmed" for Ruby the danger of her jealousy toward her sister, leading to increased guilt, depression, and finally psychosis.

Case C.—Jean and Paul were 30-year-old fraternal twins. During childhood both tended to be quiet, good students, not active in social, athletic, or other extra-curricular activities. Jean did well in college and became a research chemist. Paul, although of superior intelligence, was unable to obtain satisfactory grades in college and entered the Army, where his 4-year career was unremarkable.

Although married in 1956, Jean continued living in her parents' home. Her husband did not support her. Later that year, following delivery of her first child, she developed a paranoid schizophrenic reaction and was admitted to the hospital. On being informed of her admission, Paul became overtly psychotic, "experienced blinding insight," and "knew" just how his sister felt inside. Subsequently he became progressively more withdrawn and began a gradual downhill course.

Jean quickly recovered and returned to work. A year later, while instituting divorce proceedings against her husband, she again experienced diffuse anxiety and went on a cruise. After being approached sexually by a ship's officer, she expressed fears of an atomic explosion and showed bizarre behavior. She was admitted to the hospital and remained there 6 weeks.

At this time Paul showed an increase in anxiety with confusion in thinking. On a visit to his sister in the hospital, she told him her psychosis was meant to help him by diverting the mother's attention to herself. He concurred in this idea and sought advice from her resident psychiatrist. Paul was found to be vague and disorganized and interested in learning about hospitalization for himself.

As Jean improved and resumed her work

successfully, Paul showed further deterioration in personal habits and in July, 1959, was admitted to the hospital. His hospital course was characterized by passive resistance to treatment, and he showed only slow improvement. He felt his sister's strong interest in helping him and his mother's desire to have him return home were threats to his well-being. To date, he has shown less ability to return to independent living than his sister.

Psychological tests showed these twins to be of superior intelligence. Jean showed more evidence of paranoid thinking, Paul of phobic tendencies. Both utilized denial and showed a tendency to withdraw in the presence of emotional stress.

These twins, although of opposite sex, showed most strikingly a tendency of one twin to "identify" with the other during illness. Paul "knew" how his sister felt inside. Later, although they rationalized that their psychoses served to protect each other from the mother, the underlying hostility in the

sister could be detected. She had always felt her brother to be the mother's favorite. Paul's guilt about Jean's illness produced an increase in his anxiety and disorganization and led him to seek advice from Jean's psychiatrist. One twin seeking treatment from the psychiatrist of the other was commonly found in this series.

Case D.—John and David were 14-year-old identical negro twins who were first admitted to the hospital in June 1955. John had an acute paranoid schizophrenic reaction following the accidental death of his dog. David accompanied his twin to the hospital in order to "help him" and was found there to be depressed and concerned with ideas of guilt. He felt responsible for the dog's death and, therefore, for John's illness.

In 1952 John had been referred elsewhere for psychiatric consultation because of soiling. He showed paranoid and depressive symptoms at that time. David began psychotherapy in the same clinic the following year for a depression.

TABLE 1

IV	MAY-JUNE 1955	PARANOID, WITHDRAWN	DEPRESSED, CONFUSED
	AUG.-OCT. 1957	PARANOID, CONFUSED	PARANOID, GRANDIOSE

Ideas and feelings of sinfulness, guilt, and punishment preoccupied the twins. John was more aggressive and grandiose, had better defined goals and self-concept. David, on the other hand, viewed his role as helper to his twin.

John's psychotic episodes appeared to be more related to outside environmental stresses than his brother's. David's episodes followed threats to his relationship to John or to his dependent tie to the mother, who seemed to favor him. A brief hospitalization of the mother for physical illness two months after John was rehospitalized in August 1957 in a paranoid state led to David's being admitted for the second time with a paranoid psychosis.

A symbiotic relationship was evident in the psychoses. When John became psychotic, David became more dependent on his mother. Although David felt more equal to John when the latter was in an emotionally decompensated state, he also felt guilty and depressed, viewing John's illness as a manifestation of the hostile portion of his ambivalent feelings toward him. The recurrence of psychosis in David tended to restore their previous equilibrium.

John, the more overtly independent, became psychotic after a loss outside the twinship, the death of his dog. David, guilty about his brother's decompensation, tried to undo his guilt by being helpful. This defense failed and he became depressed. When John again became psychotic, David, who had always felt closer to his mother, was able to handle his guilt as long as he could maintain an infantile relationship with her. When she was hospitalized, he lapsed into a psychosis similar to his brother's.

The similarity of symptoms commonly found in these psychotic episodes is to be noted in Table 1.

DISCUSSION

Study of twins provides special opportunities for investigating normal and abnormal personality development as well as the particular problems that result from the fact of being a twin. Twins usually enter a similar environment in infancy although, to be sure, even with identical twins the environment is never truly the same for both. Once parents find ways of distinguishing one twin from the other, the twins can be

seen as individuals with separate characteristics as well as one of a pair. Such distinguishing features may lead to different life experiences and influence the development of significant behavioral differences in the twins (7).

Dorothy Burlingham has stated that the needs of twins for each other makes the relationship the closest known tie between two individuals. She discussed the frequent "contagion of feeling" between twins, their identification with each other, tendency to form a working team, reactions to separations, envy and jealousy, and dependence (1).

These features were seen in the adolescent and adult twin pairs of this series. In addition, problems of later maturation could be observed. Difficulties of adult heterosexual adjustment with the emergence of strong sexual and hostile feelings toward other family members and reaction formations against these were prominent. The breakdown of personality organization of one twin with psychosis was followed by a psychotic reaction in the second; and in each pair, the second twin sought help from the physician or hospital treating the first.

In addition to common patterns already noted, the following features appeared in histories of two or more of the pairs: 1. Excessive interdependence in childhood; 2. Distrust of the other twin, the family, or the world at large; 3. Hostile feelings toward the other twin; 4. Similarities of psychotic reactions; 5. Prominence of identification and the use of projection and introjection in handling anxiety.

In this preliminary investigation special attention has been focused on the established interactional patterns of the twins, the disturbances in these patterns, the attempts at compensation in order to maintain a nonpsychotic adaptation, and the failures of these attempts with resulting psychoses. In each pair a change of status of one twin was followed by a change in the other. We have made two hypotheses: first, when alternating psychoses occurred, the psychotic reactions in one twin precipitated and were related psychodynamically to the psychotic reactions in the other; and, second, the psychoses, in the absence of successful compensatory relation-

ships, represent one means for the twins to continue their relationship with each other.

Most frequently, alternating psychoses, as described above, occurred when one twin was experiencing anger toward an important person in his environment, the threat of loss of important persons or objects, or combinations of the two. In the adult pairs, conflict between a twin and her marital partner was often the apparent precipitating event.

Such stresses do not necessarily lead to psychotic states, but stress in the presence of an inadequate ego, a lack of emotional support in the person's environment, or hereditary or constitutional defects may lead to neurotic or to psychotic symptomatology.

Intense rivalries and hostile feelings with attendant distrust appeared commonly and in a number of ways. Disagreements occurred over money between one pair of twins and between one of these and her husband, whom she felt was unfaithful to her. Her accusations occurred after she had terminated a brief extramarital relationship. One twin thought she was being poisoned by her husband and by her twin's husband. The fraternal twins blamed their mother for their psychotic reactions and each believed their psychotic reactions served to protect the other from the mother.

A hierarchy of defense mechanism was used in attempting to defend against hostile feelings. Initially such mechanisms as reaction formation, undoing, or, on a more conscious level, suppression were utilized. When these proved inadequate, other defenses such as denial and displacement and ultimately more pathological mechanisms such as projection and turning against oneself were to be seen. Depression and paranoid thinking occurred commonly as symptoms in the twins during periods of psychosis.

Leonard (6) has shown the importance of identification in twins. Early in life, twins may identify with themselves even more than with the mother; the other twin is always available; the mother cannot be. Later, identification is used as one defense against feelings of rivalry. Identification with the other twin was prominent in each pair of this series; manifestations of this

could be observed during illness as well as in health. There was similarity of symptoms, awareness of the feelings of the other, and a desire to act together against parental figures. At that same time, a change in the active-passive relationship of one to the other was a source of anxiety.

The importance and fate of sexual impulses in alternating psychoses is less clear. One of the 14-year-old twins was obsessively preoccupied at the time of his first psychotic reaction with the "shrinking up" of a testicle. In his associations he related this to the mutilation of his pet dog, whose death following an accident appeared to precipitate his first psychosis. Another twin, in the course of a psychotic reaction precipitated by his sister's post-partum psychosis, became anxious about his sexual feelings toward his mother and sister. Another twin's psychosis included thoughts that her husband was unfaithful and that her oldest son might grow up to be a 'homosexual. Her sister remained free of symptoms while caring for her twin's husband and children but became depressed when they returned to their own home.

The dependency of the twins on each other appeared to be accompanied by feelings of competitiveness, envy, and anger, often intensified when there was a threat of separation. When, for example, one twin required psychiatric treatment, her sister accompanied her each time to the psychiatrist's office. He became aware that the second twin was seeking increasing amounts of his time and would have utilized all the interview time if allowed to do so.

When the dependent relationship was jeopardized by a psychiatric hospitalization of one twin, a depressive reaction often developed in the other. Burlingham has observed that twins suffer acutely when separated from each other. One twin identifies with the other who is missing, taking over his characteristics and in fact trying to be the missing twin (1).

Folie à deux bears certain resemblances to the reactions here described. The similarity of symptoms in close family members and the onset of a psychotic reaction in one following and apparently precipitated by a psychosis in the other are found in both. Psychodynamic features of this syndrome

have been reported by Deutsch(9) and others(5, 10, 11).

CONCLUSIONS AND SUMMARY

In this series, a psychotic reaction in one twin disturbed the twin relationship. When attempts of the other twin to compensate for this disturbance were not successful, an alternating psychotic reaction developed. Most often the psychoses were of paranoid or depressive type, thus emphasizing the frequent attributing of cause for the illness to the other twin and the acceptance of responsibility by that twin with subsequent guilt and depression.

There was evidence of strong rivalry between the twins during illness as well as during relatively well periods; this rivalry led to a sharing of medical and family care. The second twin was able unconsciously to exact as much help from his environment as the first. The unusually strong identification observed in normal twins appeared to carry over into illness. Ego integrity of one twin may depend on the integrity of the ego of the other.

INDIVIDUALITY IN RESPONSES OF CHILDREN TO SIMILAR ENVIRONMENTAL SITUATIONS¹

ALEXANDER THOMAS, M.D.,² HERBERT G. BIRCH, M.D., PH.D.,³
STELLA CHESS, M.D.,⁴ AND LILLIAN C. ROBBINS, M.A.⁵

Prevalent in psychiatry is the view that the process of socialization in childhood necessarily involves a series of traumata and frustrations. Thus, an influential worker in this field states of weaning that "even under the most favorable circumstances, this stage leaves a residue of a primary sense of evil and doom and of a universal nostalgia for a lost paradise"(6), of toilet-training that "bowel and bladder training has become the most obviously disturbing item of child training in wide circles of our society"(7), and of the response to siblings as involving "jealousy and rivalry . . . now come to a climax in a final contest for a favored position with the mother; the inevitable failure leads to resignation, guilt and anxiety"(8). So pervasive is the influence of this attitude that even an investigator who has himself demonstrated that sucking drive in infancy is at least in part the consequence of opportunities to suck rather than the expression of an innate oral drive states(5), in a recent publication remarks that "the weaning process, except under the most fortunate circumstances, is bound to be frustrating to the child"(14). Such statements involve the assumption that change in established patterns of behavior related to physiologic and social needs of the child is in and of itself frustrating. Thus, toilet-training with a change to the successful use of the toilet bowl rather than the diaper is viewed as a necessarily negative experience. Further, from this point of view the most benign outcome of such a change would be the minimization of trauma. Similarly, more complex parental socialization practices,

such as punishment in order to eliminate aggressive behavior in the child is categorized as anxiety-producing with the production of displaced aggression(15).

The view of socialization as a continuous process of frustration has been expressed in its most general form by Freud, in his statement that "civilization is the fruit of the renunciation of instinctual satisfaction"(11). This theoretical attitude derives from the retrospective analysis of individuals experiencing sufficient difficulty in social functioning to lead them to seek psychoanalytic treatment. The view has been extended and further reinforced by the attribution of etiologic significance to difficulties surrounding the socialization process in children who manifest various behavioral disturbances. The alternative proposition that an underlying disorder may have produced both the difficulties in socialization and the later identified behavioral pathology has only recently begun to receive serious attention(1, 3, 10).

The present report seeks to re-examine the question of the effects of important socialization experiences in early childhood on a population of 110 normal children whose development has been followed continuously from the first months of life. It therefore involves an ongoing and anterospective study in which the totality of behaviors preceding, surrounding and following such presumably significant experiences as weaning, toilet-training, the return of the mother to work, and the birth of a younger sibling, are available for analysis. An additional direction of inquiry is made possible by virtue of the prior identification of the children in terms of primary characteristics of reactivity, which have been described in earlier reports(4, 17). These characteristics which can be delineated at two to three months of age in each child and which persist in a stable form as the child grows older, we have called the primary reaction pattern. As yet, no conclusion is

possible as to whether the patterns are constitutional, environmentally determined, or a combination of both. Knowledge of this patterning permits the exploration of the influence of such initial features of reactivity on the nature of the responses to various socializing forces.

Data on the 110 children now being followed are gathered by: 1. Histories from the parents detailing the behavior of the child in objective, factual terms in the various functional activities of daily life, as well as the sequence of reactions to any special situations. These histories are taken at 3 month intervals for a year, starting at 2-3 months of age, and then at 6 month intervals; 2. Periods of direct observation at one or more points during infancy in most of the children; 3. Direct observation of the child's behavior in a standard play and psychological test situation, done at 3 years of age; 4. Direct observation of the child's behavior in nursery school, and interviews with the teacher as to the details of the child's functioning in school; and 5. A structured interview with each mother and father designed to elicit information on parental attitudes and child-care practices.

The families of our population represent a relatively homogeneous middle-class group, with a majority in various professional occupations. Child-care practices are basically permissive and child-centered, with an emphasis on satisfying the needs and desires of the child.

Details of the methodology, validation of the parental interview technique, and results through the first two years of life have been reported elsewhere (4, 17). In the 3-4 years of life that these children have been followed, a number of specific types of potentially stressful environmental situations have occurred to many of them. The details of the behavior of the children before, during and after the occurrence of these situations, as well as information as to parental attitudes and practices, have been analyzed.

The findings will be presented for each of the various types of situations studied. Since serious questions have been raised about the errors inherent in limiting observation of disturbance to the immediate function that is being influenced (9), in this study in each situation evidence of be-

havioral disturbance was sought, not only in the area directly involved, for example feeding in the course of weaning, but also in other aspects of functioning, including sleep, toileting and social responses. A second problem, namely the possibility of long delayed manifestations of behavioral disturbance, can only be explored when the children are older.

WEANING AND TOILET-TRAINING

About 40% of the mothers breast-fed their infants with the use of supplementary bottle feedings. In almost all children, the shift to the exclusive use of the bottle was accomplished gradually in the first 2-5 months. In no case was any disturbance in the infant's behavior noted with this change. Weaning from the bottle in all the children was uniformly started by offering the child sips from a cup at mealtime beginning sometime between 5 and 11 months of age. By the end of the third year 60% of the children were completely weaned, with the earliest age being at 12 months. In those children not weaned by 3 years, the bottle was taken primarily at bed and naptime, while the cup was used at mealtime. Most of the mothers of this latter group have been reluctant to make complete weaning an issue, most usually for fear of creating a sleep problem. One-third of those completely weaned accomplished this by 18 months. In many of these cases the weaning was accomplished by the child's spontaneous rejection of the bottle. In some instances the mothers persisted in their efforts to continue with bottle feeding and only stopped when they found their efforts to be of no avail. These attempts of the mothers to delay weaning were due to their fears, which they expressed openly in the interviews with them, that early weaning or toilet training might be traumatic to the child. These fears were based on the presumably authoritative statements they had heard and read as to the dangers of such early weaning and toilet-training. Some of the mothers even confessed to feeling uncomfortable and uneasy at the early weaning accomplished by the child, because they felt their friends would interpret this as evidence of rigid, outdated and harmful child-care practice. In only one case in the first 50 analyzed

has there been some evidence of significant behavioral disturbance associated with the weaning process.

Our data do not support the concept of inevitable psychic trauma inherent in the weaning process. With the permissive approach by the parents, weaning did not appear to be a source of disturbance and under certain circumstances may even have been a positive child-initiated experience. The issue might have been different if there had been rigid insistence on early weaning in the face of resistance by the child. In such situations, the effect on the child may be unfavorable, as it can be whenever the parent-child interaction is antagonistic.

In toilet-training our data are very similar to the findings in weaning. Since all the mothers in this group are permissive and are concerned with the presumed dangers of early training, only 20% started training below one year of age. The median starting age for toilet-training was 16 months. The process was usually a slow one, with the mothers stopping their attempts at training for periods of several months or more if the children objected. In most cases training was completed between 18 and 36 months. In a few children training was not successfully completed until the fourth year.

Toilet-training in the first 50 cases analyzed was accomplished without evidence of disturbance, except in one child. In a number of cases, the children themselves initiated the training, usually in imitation of an older sibling. In this function, as with weaning, the evidence does not support the concept that toilet-training is necessarily a frustrating and traumatic experience.

BIRTH OF A YOUNGER SIBLING

In 18 of the families, a younger sibling has been born since the start of the study. This has provided the opportunity to record the character and intensity of the older child's response to the introduction of an infant into the family. Over half of the 18 children showed disturbance at this event. The two main types of disturbance noted were: 1. Reversion to more infantile patterns of functioning in socialization, sleeping, feeding and toileting; and 2. Aggressive behavior toward the new baby. In 6 cases the reactions were mild and transient,

in one moderate, and in 3 prolonged and severe. Three children showed no discernible disturbance in functioning and 5 actually showed an improvement in their social responses. Thus, children reacted with various degrees of positive and negative behavior to a new sibling.

Both environmental factors and the characteristics of primary reactivity in the individual child appear to contribute to variability of response to new children. The entry of a younger sibling into the family group necessarily affects the amount of time and attention given to the child by the mother and by other members of the household. Where this change in circumstances leads to disturbance in the child, the mother is objectively unable appreciably to modify the situation as she can for weaning or toilet-training. It is of interest, therefore, that the intensity and duration of negative responses were greater in those who were themselves first children than in those who already had older siblings. For the only child the entry of a new baby into the family group seemed to constitute a much greater environmental change. Age at the time of new births also influenced reactions. There was less disturbance in those children who were under 18 months of age when the new sibling was born. A third influential factor was the degree of prior paternal involvement. In several children whose fathers had been especially active in caring for them and whose fathers continued to do so even after the arrival of the new baby, the turning of the mother's attention to the younger sibling was not an especially disturbing event. In one family where both parents were very much involved with the first child, there was no reaction when the mother took care of the new baby, but the child, a boy in his third year, developed stuttering as soon as the father began to handle the baby. As soon as the father stopped this and devoted himself again to the older child, the stuttering stopped.

On the organismic side, qualitative analysis of the data has shown a definite relationship between the characteristics of primary reactivity in the child and the type of response to the birth of a sibling. Those children who from early infancy on showed mild, positive regular responses with quick adapt-

ability to new stimuli, such as the bath, change in sleep schedule and the introduction of new foods, manifested a similar pattern with the new baby. In this group, disturbances were minimal or non-existent. On the other hand, those children characterized by intense, negative and irregular responses with slow adaptability tended to show greater and more prolonged disturbances after the birth of a sibling.

MOTHER'S RETURN TO WORK

Six of the mothers returned to full-time professional work when the child was 2-3 months old. There was intense, prolonged disturbance in one child and none observable in the other 5. The child who was upset had intense, irregular, negative and non-adaptive responses as the over-all primary pattern. The other 5 who are now all in the fourth year of life, have shown no significant disturbance in functioning. The primary reaction patterns of these children have been of the regular, mild, positive and adaptive type.

PARENTAL PRACTICES AND ATTITUDES

A quantitative analysis of our data has confirmed other studies (2, 12, 13, 16), indicating a lack of any one-to-one correlation between any specific parental practice and its effectiveness. In our child-centered families the mothers have most usually tried to meet the child's demands, and where this has not been possible have tried to alter the stimulus or the situation rather than insist on the child's alteration of a negative response. In spite of parental similarities of approach, the responses of the different children in the areas of sleep, feeding, toilet-training and social restraint have shown wide variation. Preliminary impressions, which await confirmation by a fuller analysis now in progress, are that this variability in responsiveness may be related both to the primary pattern of the individual child and to the over-all attitudes of the parents.

It also appears that while the parental attitudes do play a very important role in influencing the child's development, the direction of this influence is significantly affected by the child's primary reaction pattern. For example, several mothers have

been pressuring and domineering in their approach. In two cases, the children have developed strong negativistic trends, but in a third case it is significant that the child has become acquiescent to his mother's demands and even submissive. The first two children have intense, negative and non-adaptive primary reactive characteristics, whereas the third is mild, positive and adaptive.

It has also been of great interest to observe the progressive crystallization of specific parental attitudes related to the primary reactive characteristics of the child. Where the child's primary pattern has made his care easy, the mother has often shown a much quicker and more intense development of positive attitudes than in those cases in which the child's primary reactions have made his care more difficult and time-consuming. This influence of the child on the parent has been most dramatically evident in two families where there are twins who showed differences in patterning of reactivity from early infancy on. In each family, the mother, who started with the same attitude toward the two infants, has developed increasingly dissimilar responses to them as they have grown older. In large part, these attitudes are based on her reaction to their primary differences. In 3 other families with twins with similar patterning each to the other, this differentiation of parental attitude has not been evident.

OTHER SPECIAL EVENTS

Five children were hospitalized during the first two years of life for various illnesses and operative procedures. The mothers stayed at the hospital with the child either for part or all of each day. No significant disturbance related to the hospitalization was evident in three children after the return home. In one child there was a moderate reaction which appeared related to the limitations imposed by a hip cast. Only in one child was there marked disturbance. In this case the mother was very pressuring, overprotective and at the same time hostile to the child, and during the one week period of hospitalization literally insisted on staying with her day and night.

Ten children have had to wear an orthopedic foot bar at night for several months

or more during the first year of life. After the initial period of adaptation, which took several days to two weeks, no persistent disturbance in reaction to this restraint developed, except in the same child mentioned above with severe reaction to hospitalization.

Separation or divorce of the parents has occurred in 4 families, in each case before the child was 2 years of age. No significant acute disturbance has occurred in any of these children, though, of course, no prediction can be made as to any long-term effects.

DISCUSSION AND CONCLUSIONS

The above data indicate that the character of the response of a young child to specific situations or to the over-all attitude of the parent is the result of the interplay between environmental factors and the primary reaction pattern. With certain events, such as weaning and toilet-training, the parent can guide and modify the approach in accordance with the reactions of the individual child so that disturbance is kept to a minimum. With the birth of a younger sibling, where the parent does not have this degree of control over the situation, the possibility of disturbance is much greater. The influence of the child's primary reaction pattern is more obvious in the marked variability of response of different children to this event.

On the other hand, the data do not support the concept that weaning and toilet-training are necessarily traumatic, an assumption usually based on the hypothesis that these events cause frustration of libidinous drives. Such frustration, and such fixed drive states are not evident in the behavior of the various children in this study. This is especially highlighted by the number of cases in which the child, instead of clinging to such presumed instinctual gratifications, initiated weaning or toilet-training himself over the mother's resistance.

Further, our data do not support the prevalent idea that the process of socialization in the young child necessarily involves a sequence of frustrating and traumatic events. This concept is based on the assumption that it must always be a negative ex-

perience for the child to give up an activity such as sucking which is associated with the gratification of a biological need, or to lose a part of the mother's time and attention if she returns to work or a younger sibling enters the family, or to change initial patterns of activity as the result of training, such as in bladder and bowel evacuation. The learning of the many social restraints necessary for the child's safety, for the recognition of the needs of others, and for the prevention of damage to household objects, is also considered to involve primarily the frustration of the child's own drives. Absent from these various formulations is the concept that the processes involved in socialization may have very important positive aspects for the child. The learning of a new activity, the mastery of a function such as sphincter control, the stimulus for changes in behavioral patterns provided by the identification with and desire to imitate a parent or older sibling may have important positive effects on the growing child.

The wide variations in response to similar environmental situations occurring during the process of socialization shown by the children in this study indicates that it is impossible to make any generalization as to the effect of such events that will be valid for all children. Every experience is an individualized one for each child and its psychological influence can be understood only in terms of the environmental context in which it occurs and of the primary characteristics of reactivity of the child.

Finally, it is important for parents to know that their basic activities with the infant, such as weaning, toilet-training, and the teaching of various restraints and prohibitions, are not necessarily traumatic and frustrating to the child, and may even be positive experiences. The same is true of events which result in the diminution of the mother's time devoted to that particular child, as with the birth of a younger sibling. Prevalent psychiatric attitudes have led innumerable mothers to feel apprehensive as to the potentially harmful effects of these activities and events on the child, so that the normal processes of child-care take on the aspect of a hazardous and treacherous project(2). This apprehension was graphi-

cally demonstrated by the mothers in our study population who resisted the child's spontaneous demand to be weaned early, for fear of its consequences. The reassurance that the normal processes of socialization are not necessarily fraught with all kinds of psychological dangers for the child has proven very helpful to these mothers, and can, with profit, be extended to all those who have suffered from the influence of incorrect theory,

DISCUSSION OF TWO PAPERS¹

F. J. KALLMANN, M.D.

Since several papers presented at this meeting conveyed an intriguing object lesson in the versatility of the twin study method or, more specifically, of the many investigators now using it, I appreciate this opportunity to comment on them *en bloc*. A definite advantage of this arrangement is that instead of being forced in my brief remarks to harp on the obvious procedural and interpretative limitations of psychiatric twin studies, I can place the emphasis on their matchless potentialities. To make the most of them, however, twin study projects call for a representative series of twins, amenable to the employment of appropriate statistical techniques. The statistics describing such a sample are computed from twin index cases rather than nonrandomly collected twin pairs.

Twins in general have long been known to be fascinating research subjects, irrespective of the fact that they offer unique opportunities for combined cross-sectional and longitudinal studies in a family setting. However, single observations on twins are rarely significant in themselves nor are twin data as such less defenseless against abuse than any other set of statistics. To paraphrase recent comments by Morison and Li, facts about twins do not give us a direct sense of cause and effect, nor are twins as a research species so uniquely unique that they defy any attempt at statistical treatment.

Whatever may be said about statistics generally, it cannot be doubted that reliance on statistical techniques will go a long way towards helping a psychiatric twin research worker, as much as it does any other investigator in the behavioral sciences, to detach himself from an intuitive sense of his material. In other words, in order to have a

better understanding of the complex etiology of disordered behavior patterns, contemporary psychiatry needs scientifically validated facts more urgently than a great number of casuistic observations which seem somehow compatible with a neat hypothesis.

To avoid possible misunderstanding, I hasten to say a few special words of praise for one of the papers to be discussed by me, that of Dr. Chess and her co-workers on the variability of the young child's response to similar environmental situations and, in turn, the progressive crystallization of specific maternal attitudes in response to the primary reaction pattern of the child. While the emphasis of this carefully conducted study has been on single-born children, it is certainly of interest, and in agreement with many other observations, that in families with twins who showed dissimilarity in behavioral patterning from early infancy on, there was a substantial difference in the effect exerted by the children on the mother. By the same token, it was to be expected, that no comparable differentiation of maternal attitudes could be observed in the families of twins who were similar in their primary reaction patterns.

For a longitudinal record of these twin histories it would of course be helpful to have all essential zygosity data specified in detail. The same stipulation applies to the findings in the other twin studies presented in this section. The given observations are based on a combined total of seven pairs of twins with an assortment of at least eight different forms of psychiatric disorder. The age range of the twins was from 12 to 45 years, and one of the pairs was of opposite sex and therefore dizygotic.

Regarding the rather vague reference to our finding of a higher schizophrenia risk figure for two-egg twin partners than for "non-twin siblings," it should be pointed out that the risk difference between full siblings and all dizygotic cotwins extended from 14.2 to 14.5 per cent in the 1953 material cited, and from 14.3 to 14.7 per cent

¹Two papers presented at the annual meeting of The American Psychiatric Association in Atlantic City on May 10, 1960: 1. Stella Chess, Alexander Thomas, and Herbert Birch: *Individuality in Responses of Children to Similar Environmental Situations*; and 2. E. Gardner Jacobs, and Alvin M. Mesnikoff: *Alternating Psychoses in Twins: Report of Four Cases*.

in an earlier analysis published in 1946. What has not been mentioned by Dr. Jacobs and Dr. Mesnikoff is that in the same families, the morbidity risk of the step-sibs and half-sibs of schizophrenic twin index cases varied from 1.8 to 7.0 per cent. At any rate, it should not be inferred that the genetic theory of schizophrenia depends only on the interpretation of concordant twin data.

Another aspect to be considered is that in our original sample of 691 schizophrenic twin index families, simultaneous occurrence of schizophrenic symptoms was observed in only 17.6 per cent of one-egg twin pairs. In about one-half of this consecutive series of pairs—52.9 per cent, to be exact—there was a difference in disease onset of one month to four years, while in over one-quarter the difference observed was from four to twelve years. Significant dissimilarities in symptomatology were seen especially in twin partners with a definite disparity in age of onset.

Even more striking was the finding that similarity and dissimilarity in environmental constellations were almost equally distributed in the series of discordant pairs. More specifically, 49.3 per cent of two-egg co-twins remained free of schizophrenia although they had shared the same environment with a schizophrenic twin; and approximately one-quarter of one-egg pairs (22.4%) became concordant without similar environment. A more recent twin study of preadolescent forms of schizophrenia confirmed the nonexistence of a simple correlation between inadequacy of the parental home and an early onset of a schizophrenic psychosis.

The last point to be covered may be a matter of semantics to some people, but it happens to be a pet peeve of mine of rather long standing. It concerns the introduction of still another synonym—the phrase “alternating psychoses”—for one of the clearly anachronistic expressions of modern psychiatry: *folie à deux*, variously referred to as induced insanity or psychosis of association.

Originally used by Lasègue and Fabret in 1877 to describe the transference of delusional ideas from a psychotic individual to an intimate and submissive associate, re-

placing such older terms as infectious insanity and psychic contagion, the concept of *folie à deux* was later stretched so far as to be applied to the coexistence of any mental disorders of a similar variety in two or more persons who seemed closely enough associated. For example, the term was frequently employed either to describe or to explain similar schizophrenic or depressive symptoms in twin partners or two other members of a family unit. Equivalent diagnostic labels used were collective, contagious, simultaneous, reciprocal or double insanity; mystic paranoia; and induced, influenced, imposed, communicated or associated psychosis. In this manner, and subtly reinforced by the equally ineradicable belief in the inheritance of acquired characteristics, the concept of *folie à deux* helped to perpetuate the notion of a magic phenomenon producing mental disease through personal contact.

Many years ago (1946), for the sake of creating a more objective attitude toward the phenomena and techniques of psychiatric genetics, I suggested limiting the term *folie à deux* to the transference of circumscribed delusions between closely associated but unrelated persons. With our present knowledge still far from enabling us—with or without intuition—to separate the interacting effects of genetic and nongenetic elements in the etiology of behavior disorders in consanguineous settings, my original suggestion still holds in 1960. If an unbalanced chromosome complement due to non-disjunction of chromosome 21 occurs more frequently in the child of an older woman than in that of a younger one, a conceptual preference for alluding to the mother's age as a sociopathic factor will be of very limited value in understanding the etiology of mongolism. In such instances, time alone will be able to determine the validity of a tentative hypothesis, however attractive or appealing it may have been at the time when it was formulated.

May I conclude my comments with a word of thanks to the various sets of investigators who contributed to this interesting session. All reports were thought-provoking and, therefore, of definite merit.

BEHAVIORAL CATEGORIES OF CHILDHOOD¹

J. FRANKLIN ROBINSON, M.D., LOUIS J. VITALE, M.D.,
AND CARL J. NITSCHKE²

A group of descriptively delineated behavioral categories of children is presented for critical review. We are interested in ascertaining whether other professional workers will recognize these behavioral patterns. The patterns are presented tentatively as they have appeared in clinical practice with children rather than as a final formulation.

Fear or anxiety is an inherent reaction to a new and important situation, and personality is patterned to a significant degree by the manner in which an individual responds to these feelings. As a child is introduced into a treatment situation, he will be apprehensive, and we have been accustomed to describing the manner in which he attempts to handle himself as fear or anxiety is aroused. Such reactive patterns are confirmed as the therapist becomes intimately acquainted with the child and constitute the framework in which the child's behavior is examined. The patterns are surprisingly consistent for a given child.

Some years ago, we reviewed a large number of case records and listed the behavioral patterns which were described. With usage, the following categories became easily recognized: 1. Active Superficial (including children with circumscribed interest patterns), 2. Openly Antagonistic (actively antagonistic), 3. Active Control, 4. Passive Control, 5. Passive Apprehensive.

These categories do not correspond with classical nosological groupings, but can be recognized as patterned tendencies within the group of transient situational reactions, psychoneuroses, personality or character disorders, the organic and intellectual defect states, and the normal child.

We are not convinced of the inclusiveness

of the categories and would entertain suggestions for additions or alteration of the groupings. They have had considerable use within the program of the Children's Service Center, and we urge your consideration of them.

A category might be viewed as a pattern of defense. The positive aspect of a defense reaction is that it is a way the individual has discovered of responding in certain circumstances. Such patterned responses become characteristic for each child. On occasion, a child may react with a variety of the responses listed, and indeed with other defenses, but it is our impression that there is a tendency to follow certain patterns in a repetitive manner. The categories have singled out a feature of the accustomed responses of the child, which dominates his reactive patterns. We have concluded that children do not from time to time alter their responses to utilize extensively a variety of the categorical patterns.

Activity refers to the manner of a child's approach to interpersonal relationships rather than to the quantity of motor discharge. In the active group, the child directs his actions with a secondary concern for the response of the other individual. The passive child does not initiate issues, but responds in his accustomed manner as he is required by the activity of the other person.

The *actively superficial* child presents an apparent shallowness in emotional response and is difficult to engage in meaningful discussion of his attitudes and emotions. He may converse on impersonal topics, but is not essentially concerned with communication and is evasive or disinterested when attempts are made to discuss his personal feelings. Such moves are countered or anticipated with self-centered activities or talk.

There is a tendency to deny the existence of troubled feeling or of behavioral difficulty. The child expresses positive or pleasant feelings, but does not reveal negative, hostile, or openly aggressive feeling. He is superficially conforming, ready to please

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Director, Asst. Psychiatrist and Chief Psychologist, The Children's Service Center of Wyoming Valley, Wilkes-Barre, Penna.

or be obliging, and unwilling to invoke displeasure.

There may be an air of self-satisfaction. Such children may be popular because they do not offend or challenge. They, however, avoid close friendships.

The following case illustrates this category :

Case 1.—Boy, age 10 years. A good looking, likeable boy, John adjusted to camp readily. Although he played games and joined in activities, he was never part of the group. His relationships were superficial with the children and staff. He was not truthful and admitted little or no responsibility for stealing or leaving camp grounds without permission. John always had a story to cover his actions. If he had stolen money, he would say that his father had sent it to him. John did not talk freely of his parents and did not write to them, although he always looked for mail.

The *actively antagonistic* child is perhaps more aptly termed openly antagonistic. He is hostile, negative or defiant in his approach to people and situations. He does not conform and stirs rebellion in others. His fear may be obvious, but is denied, even when he is aware of it. Such children may engage in antisocial acts and constitute one group of delinquents.

He challenges and invites others into struggle. He denies personal problems, and projects the difficulty onto others. He seems to fight against a friendly approach to him. He has a need to oppose and is ever ready to defend himself or attack when he is threatened. He cannot relate easily at a positive level.

Case 2. (Excerpt from an initial interview.) —Boy, age 5 years. "Mrs. Depew is going to bring her nice little boy down here and I will have a fine time. Her boy fights." I say that I thought Andy was the one who fights. He says, "My name is Andrew. Do you mean me?"

"I'll tell you something about Dexter Depew. The kids in school call him 'Stinky,' and next week I am going to wear something and scare you—my cowboy suit." He continues, "Hey, do you want me to come down here any more?" I say that I thought he came down here because he had a job to do. He continues, "I'll beat you up. I can be anywhere I want to."

One notes the manner in which this boy meets a new situation with an habitually aggressive response.

Control is a practice of limiting or prohibiting the activity of the other person, so that one is not called on to respond in a manner determined for him. If you allow another person freedom of action, you must react to his directional moves. The controlling patient avoids challenge and the accompanying fear or anxiety by keeping matters in his own terms and restricting the initiative of those who would associate with him. Such control of the behavior of another person is distinguished from so called self-control.

The *actively controlling* child attempts to dominate and direct those about him so that fear will not be aroused. He is demanding of others, but is himself dissatisfied. He does not accept limits. He becomes querulous or petulant, when compelled to attend or respond. He is disturbing in a group, because of his persistent drive to compel others to respond to his demands. He will act in a group only on his own terms. The important distinguishing feature is the active determining influence in the group or in a personal relationship.

The following case excerpt is illustrative.

Case 3.—Boy, age 8 years. "Don't call me Morton, call me John." He doesn't like Morton. He makes people call him John. When I open a window, he says, "Don't open the window; it is too cold." Then he looks at the chairs and says, "Oh, if I sit on one of those chairs, I'll bust it. Yes, I'll bust it. I'll cave those chairs through, once I sit on them." I say that I imagine they are strong enough to hold him, but I suppose he feels a little frightened about using those chairs. He says, "I have to sit down, but I'm not going to."

One notes the manner in which this boy dictates that he be called by a name other than his own. He does not allow the therapist to open a window, and expresses his reluctance to participate freely, even to the extent of using a chair.

Passive control is sometimes more difficult to distinguish, but becomes apparent when the child's behavior is examined over an extended period. Such children initially

may appear to be emotionally unresponsive, but do persistently influence the activities of the therapist or those about them. They differ from the active superficial group in that they are not ready to conform or be obliging. They are not deterred by the displeasure of others. They differ from the active control group in their reluctance to express evident antagonism. While passive, they are not neutral in a relationship, and do control and influence the behavior of those about them.

There is little overt indication of emotional turmoil or concern. They appear to lack initiative or spontaneity. Discussion of personal feeling is avoided. Verbal contact is at a minimum and they may hold to periods of silence or inactivity. One may gain an impression of an emotional defect because of the unresponsiveness and the child's inability to communicate.

Case 4.—Girl, age 10 years. She doesn't feel very good about herself, therefore, she should change her habits. She says that she tears her clothes. "I don't say I am mad, I just do it." I say, "Tearing your clothes is the way you tell people you are angry." She says, "That's the way I do it; I don't say it. I keep what I feel right inside." She says, "I only think it inside; I don't seem to say it." I say, "That sounds different from tearing clothes, that sounds like trouble in really getting some of these feelings out." She continues, "I guess that's my part. I talk back in one way—sometimes it's like talking back. Mommy says to do something, I don't say I won't. I do in some way say I won't. She'll say there were 14 girls, I'll say there were 12. Then she'll think it over and say there were 12, and I'll keep on saying there were 14. I'll say I want it that way. I think I'm right and I get mad."

The *passive apprehensive* group is easy to recognize. The fear or apprehension is evident to the patient and to others. The child is reluctant to express antagonism and to act spontaneously or demonstrate initiative. He expresses his apprehension readily and openly. He differs from the passively controlling in that he conforms and follows directions. He is not an effective influence in the group, and usually prefers younger associates.

The passively apprehensive child is distinguished from the passively controlling

child most readily because of his evident emotional distress. His fear is diffuse and easily discerned by the therapist. He appears helpless and cries easily when challenged. He may be aware of his fear and unable to act decisively. He asks for direction from the therapist, but his response is passive and uncertain.

Case 5.—Boy, age 8 years. Then he turns to me and says, "They haven't gone yet. If they have, I don't know what I'll do. I'll be scared." I say, "Maybe you feel scared just being here." He asks me if I know the way to his home. I say that I think he will get home all right. He says he's not going to stay here. "When am I going down?" Then he cries and says, "I'm going downstairs." I ask him why he has come—that children usually come here to get something done. He says, "I'm not going to do anything. I feel like crying." He starts to cry and says he wants to go home.

The categories are useful in communication among clinical staff members. In collaborative work, with a number of professional workers involved in the efforts to help the child, unity of effort is important. The categories offer a ready means of stating certain features of a child's reaction pattern in a more organized manner than listing of symptomatic behavior, and in a manner not yet committed to an assumption or speculation about the psychodynamic organization of the child. The emphasis is directed away from the behavioral symptoms to the nature of the child's efforts to react to his emotions.

The categories are also helpful in defining with the parents the nature of the child's difficulty. Effective work with a parent calls for some accord between the psychiatrist or clinical team and the parent in the formulation of the child's problems. This must be reached in terms which are comprehensible and meaningful to the parent, and which center attention on the emotional aspects of the difficulty (*e.g.* the child's fear, and his efforts to handle it) rather than the troublesome behavior itself.

An openly antagonistic child can be seen as one attempting to act in the face of fear, rather than as primarily hostile or antagonistic to his parents, his friends, his teachers, *etc.* The emphasis is on his underlying

apprehensiveness and uncertainty, rather than his overtly aggressive behavior, which may indeed be reinforced when one reacts to it in kind. The controlling child can be seen as protecting himself rather than being determined to direct and compel the affairs of those with whom he associates. Such an early declaration of the psychological aspects of the child's behavior enables a more constructive initial approach to the understanding of the child, and does not preclude an altered or more thorough understanding of the child's motives and patterned reactions, as work progresses.

If the patterns outlined in the categories can be recognized by other workers, they would be valuable in statistical or research studies. At this point, their chief value will be as a stimulus towards the delineation of groupings, which are applicable in childhood. We have a long road to travel to arrive at a useful classification of childhood disorders. Many of the suggestions that will be proposed will be discarded, but we cannot longer delay efforts to find nosological groupings which incorporate the features of the common disorders of childhood. Especially in the situational reactions, psychoneuroses, personality and character disorders, a refinement of classification is needed with the aim of reaching groupings which have a common acceptance throughout the children's field. The task will not be accomplished by either a single or isolated group of workers. At this point, suggestions for new approaches should be encouraged, as well as critically examined.

The delineation of a syndrome, in which certain psychological features are emphasized, may lead to the recognition of a characteristic developmental or life history. This is illustrated in the manner in which we have developed an increasing understanding of the group of children designated as having circumscribed interest patterns(1).

These children were seen initially as a group who had done well in treatment and who demonstrated withdrawal of a lesser degree than was encountered in early infantile autism, but who had restricted favored interests or activities. They were

not psychotic and the benignancy of the condition was indicated by the relative absence of bizarreness and the usefulness or comprehensiveness of the circumscribed interests or activities.

We recognized shortly that all of such children fell within the category of the actively superficial. Indeed, it was the superficial aloofness which initially concerned the parents. The aloofness was evident in the pre-school years when the child had his earliest opportunities for group experience.

With the development of the special interests, parents were encouraged, and hoped that the children were becoming involved in the activities of those about them. The superficiality or partial withdrawal was maintained. The children socialized to a limited degree. Teachers were troubled about the children when they failed to participate in classroom activities. It was usually through discussions with teachers (school and Sabbath school) and recreational leaders that the parents developed a second period of concern about the child. Referrals were accordingly made between the ages of 8 to 12 years with surprisingly few referrals at earlier ages.

A recognition of these features of the child's psychological make-up and development led to the observation that many of the parents had themselves a superficial or aloof quality. The nature of the child's interests seldom followed those of the parents. Perhaps a reluctance for emotional involvement was necessary to enable an evident social deviation in a child to continue over a number of years. In any event, it has become evident that work with most of the parents of such children calls for a real measure of certainty and direction in the early stages.

We do not know that each of the categories described predisposes toward a certain type of developmental life history. If this were so, the categories would indeed be useful, if empirical, groupings. We are suggesting that a search for syndromal groupings of psychological and behavioral characteristics may be one of the steps which will lead to a useful classification of childhood disorders.

CONCLUSIONS

1. Five descriptive categories of behavior in childhood have been outlined.
2. These categories have proven useful in intra-staff communication, and in the organization of work with parents.
3. These or other groupings of symptoms or behavioral features may lead to the

recognition of clinical conditions, which can achieve general recognition or acceptance leading toward a practical classification of childhood disorders.

RESULTS OF MENTAL HOSPITAL TREATMENT OF TROUBLED YOUTH¹

DONALD M. HAMILTON, M.D., ROBERT A. MCKINLEY, M.D.,
HARRY H. MOORHEAD, M.D., AND JAMES H. WALL, M.D.²

In the study and treatment of troubled youth who have come to the attention of society and its service agencies during the years since World War II, we have selected to review the life histories of 100 young males between the ages of 14 and 19 admitted to The New York Hospital, Westchester Division over a period of 10 years. They represent the consecutive admissions of this age group from 1946 to 1956. The hospital has been called upon to share the responsibility of studying, treating and attempting to restore these young people to a productive and satisfying place in life. Their difficulties have grown more severe as time goes by and the schools and courts have been most cooperative in the arrangements for admission and the treatment and rehabilitation of these young people. This is the first of many studies by the entire medical staff and personnel of the hospital. The aim of this research is to acquire an increased understanding of the problem as it relates to the individual patient, his family, the home, schools, and social environments to which he is restored. Through this understanding, improved methods of management and treatment are being developed.

The average age of this group at the time of admission was 17. Most of them came from small family units: 19 were only children, 30 had only one other sibling. Sixty-three or almost two-thirds were first male children in the family. The pressure to succeed was extraordinary and a source of paralyzing anxiety to many. The families were generally well-to-do with better than average educational and cultural opportunities. There were 50 Protestants, 28 Jewish, and 22 Roman Catholics. There were 54 who showed psychotic reactions in the family history. Twenty-five had parents who were hospitalized for psychoses. These pa-

tients were impressed by the disturbance created in the home and by the separation from the parent. There were only 10 from homes broken by divorce, separation, or death of one of the parents, but over 90% showed a lack of harmony between the parents. The father frequently failed to set a healthy example for identification and in exerting firm leadership. Fathers being away in military service during the infancy and early childhood was most traumatic. While the father was away the mother commonly went to live with her parents and the early home environment was predominantly female. Upon returning from war service where masculine virtues were emphasized, the fathers often gained the impression that their sons were spoiled and effeminate. They tended to enforce a Spartan discipline, sometimes of a cruel nature. Such fathers had not developed any real relationship with their sons. Many commented that they had never felt close to their child; some even doubted the child's paternity. Patients growing up in this situation felt rejected and reacted with a variety of psychopathological patterns depending on their temperament. Feminine identification with exaggerated passive dependent needs was a frequent finding. Upon reaching adolescence this was the source of great conflict. Hostile, rebellious, and even delinquent behavior was often displayed in an attempt to compensate for doubts concerning their masculinity.

Of significant importance was a type of mother who was immature, indulgent and even seductive in her attitude toward the patient. This was manifested in two-thirds of the mothers by prolonging infantile dependence and by too much fondling. Some mothers undressed and bathed before their adolescent sons; others permitted their sons to sleep with them. These mothers and sons were often conscious of the sexual excitement induced. The psychotic symptoms precipitating the hospitalization of many pa-

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² From the clinical services of the New York Hospital, Westchester Division, White Plains, N. Y.

tients were alternating periods of hostility and erotic advances towards the mothers. Five of these mothers, conscious of their own incestuous feelings, became psychotic and required hospital treatment.

Infancy and early childhood were commonly marked by serious physical difficulties including birth injuries, repeated upper respiratory infections, allergies, feeding problems and operations. These appeared to interfere with normal physical growth and to retard the development of normal healthy relationships with members of the family and playmates. Over 75% were shy, isolated, poorly coordinated and lacking in strong spontaneous feelings. The group as a whole found it difficult to invest interest in their surroundings, school work and group activities.

Although their school work was average in 75%, they were not up to the family standard and felt inferior to other members of the family and classmates. One third of the group had Intelligence Quotients ranging between 90 and 100 while parents and siblings were within the superior intellectual range. Discouragement at their relatively unsuccessful school work was associated with a lack of application, falling behind, and dislike for school. Twenty-five per cent were above average and were compulsive and perfectionistic about their school work. The latter did better in responding to hospital treatment and a greater proportion of these patients recovered.

There was noticeable unevenness in personality development. Being isolated, they did not feel secure in the family group or at school. Over-compensation in preoccupation with unhealthy and impractical intellectual activities along with philosophical, religious and mystical ruminations was common. Many became absorbed in solitary hobbies. Failure in emotional maturing and socialization led to increased withdrawal and a tendency to act out aggressively against parents, teachers and less commonly playmates.

The following case illustrates these points :

John, whose mother became psychotic after his admission and required hospitalization, was born while his father was in the armed services. He had been a quiet, beautiful infant and child,

closely attached to his mother. He enjoyed combing his mother's hair well into his teens and spent hours shopping for "just the right present" for his mother or his aunts. The father declared he had never felt close to, or understood, his son and favored an older sister born several years before the father went into the armed services. In an attempt to make a man of his son he enforced a rigid discipline and wanted to send John to a military school. The mother thwarted this move. At adolescence John suddenly became rebellious to all authority, played "hookey" and was suspended from school on several occasions because of his undisciplined behavior. He joined a gang at 14 and was involved in petty thieving. He adopted the coarse manners, speech, and accent of the so-called "hood" group in his community. When he assaulted his mother and threatened his father with a knife when the latter intervened, he was hospitalized. In spite of his "tough" manner he spent much time preening his hair and admiring himself in the mirror.

The average duration of difficulties of patients prior to admission was 2½ years. The stress of adolescence was an important precipitating factor. At this time there was a strong drive to be independent. They were unable to feel close to anyone and were preoccupied with sexual matters. The illness was precipitated by attempting to adjust to the first year of preparatory school or college in 30 patients. In 10 the illness was closely associated with serious sickness of one of the parents. The first sign of abnormal behavior followed severe virus infections or operations in 15. Ten were disturbed by a move to a new environment to which one or both parents also were reacting with signs of stress. One-third worried that others believed them to be homosexual or feared that they could not control homosexual tendencies in themselves. In their state of insecurity 40 became involved in stealing from their families and in minor pilfering in their neighborhood in an attempt to gain a sense of status or to "rent" friends as one so aptly declared. Only 10 had come to the attention of the law and in all these there was close cooperation with the courts and probation officers.

All were admitted on voluntary status, on their own signature or as voluntary minors on the application of one of the parents. The mental picture was largely that of

adolescent turmoil. Eighty-one were diagnosed as schizophrenia, 66 as catatonic, 8 simple, 6 paranoid, and 1 as hebephrenic type. Ten were diagnosed as psychopathic personality with asocial trends, and these differed from the schizophrenics in their impulsive acting out. They were more aggressive and straightforward in their acts of stealing and aggression, whereas those diagnosed as schizophrenia showed more fumbling and disorganized forms of stealing or impulsive actions. Depressive and suicidal trends were encountered in 35, usually associated with ideas of guilt and preoccupation with a sickly religiosity closely related to concerns over masturbation, homosexuality, sadistic heterosexual fantasies, or fears of losing control.

The schizophrenic reactions were always associated with trends involving projection of homosexuality and delusional thinking. The psychological tests such as Rorschach and other projective tests confirmed the clinical observations and evaluations. Eight were diagnosed as manic-depressive reactions and one as psychoneurotic.

Physically the group was interesting. Mention has been made of physical difficulties in infancy and childhood and how these factors resulted in the development of a weak ego structure, manifesting itself in poor interpersonal relations, little spontaneous interest in the environment, and a lack of commitment to work and play. At the time of admission 50% were poorly coordinated and awkward. Thirty showed some form of allergy, and 25 were undernourished. Of interest was the occurrence of myopia in one-half of the patients, and an equal number had acne, dilated pupils and vasomotor symptoms such as cold, clammy hands, and excessive and odorous perspiration associated with exertion. Only 9 showed abnormal EEG tracings and these were not associated with any particular diagnostic grouping. Two were so abnormal with clinical findings suggesting epileptic equivalents that anti-convulsant medication was administered and proved helpful.

A general disheveled appearance and the tendency to be non-cooperative in manners, clothes, style of hair cut were characteristic. Many of them had long hair which they handled and combed, frequently preening

before mirrors and openly admiring themselves in a vain and effeminate way. At first they resented the structured environment where proper clothes and hair cuts were insisted upon. In their turbulent and rebellious desire to be independent they resisted the program of socialization, good manners and group participation in all activities. The physicians gained their confidence through firm support, psychotherapeutic efforts and consistent insistence upon keeping up to all expected of them in a hospital setting. Women nurses won their respect and created a homelike environment. This has been observed in all hospitals where women nurses have gradually replaced male nurses and attendants, although among acutely disturbed patients the mature male nurse plays an important and necessary role. The relationship developed with male members of the physical education and occupational therapy departments afforded opportunities for healthy male identifications. As this identification proceeded, there was a notable decrease in acting out behavior.

The following is an illustrative example :

John, referred to above, tended to disrupt occupational therapy classes by his rebellious and distracting behavior when supervised by a female therapist. However, he worked productively in printing and the wood shop under consistent and firm male guidance. At physical education he tried to hide his fears of any body contact sports and his general ineptness at athletics by standing on the sidelines making belittling remarks. A younger male physical education instructor gradually gained a relationship with him and encouraged him to develop his chest and upper arm muscles in individual exercises involving the rowing machine, chest weights and the punching bag. He was gradually introduced to ping pong, bowling, and finally group sports such as volley ball and soft ball. He eventually became the catcher on the soft ball team. Coincident with these accomplishments and interests was the gradual development of an improved and healthy relationship with his father.

In addition to skill in athletics, greater emphasis was placed on learning to enjoy group activity with consideration for others and achieving a feeling of belonging and being wanted as a member of the group. Most of these young men are afraid of the

role that must be assumed at social dances and some time is required to reach the point of full enjoyment of these functions. The same is true of group singing, card parties and other social gatherings of mixed groups. In occupational therapy great patience is required to assist them to achieve satisfaction in constructive activity. The same is true in the music and library departments. Many of the patient's reactions on the halls and in the various program therapy departments become topics for discussion in the psychotherapeutic interviews. In psychotherapy the interview method is employed with emphasis on dynamic and interpretative psychiatry. On the basis of a good relationship with his physician the patient is able to review his own personality development and learn better ways of managing in all spheres of his life.

About two-thirds of parents needed psychiatric help. Many on their first contact with the hospital appeared demoralized. At the time of admission they were anxious, sleepless, and overwhelmed by feelings of guilt over being the cause of their son's problems. They typically alternated between sobbing helplessness and loud and hostile berating of the patient for being vicious and ungrateful. Most parents were uneasy in their early relationship with the psychiatrist, misinterpreting questions involved in history taking as indications they were being accused of causing the patient's illness. Parents tended to blame each other for the patient's illness, bickered at home, before staff members, and on occasions even in front of the patient when visiting. All of them were given ample time by the physicians of the hospital and some were referred to psychiatrists in private practice when this was indicated. The Social Service Department was of inestimable value in working with parents. Efforts were directed particularly towards engaging the fathers in the understanding and rehabilitation of the patient.

Much of the acting out and delinquent behavior as well as the exaggerated heterosexual and homosexual concerns noted among this group were directly related to their difficulty in achieving male identifications. The situation was often further complicated by the hostile and rejecting at-

titudes of fathers. Fathers were coached as to appropriate and supporting responses to the patients' symptoms on the background of greater understanding of the meaning of these reactions. Fathers were encouraged to visit their sons without the mother's being present. During the convalescent phase of treatment, visits to sports events, fishing, hunting, vacation trips with the father as well as working together on projects of mutual interest were most helpful in the rehabilitation of patients.

Visits of mothers, particularly during the early period of hospitalization, were frequently limited as they tended to reactivate passive and dependent needs in the patient to which he responded by increased tension and an exaggeration of symptoms. At this time in spite of careful discussion and preparation, mothers often reacted to the psychiatrist as though he were intimating they were the cause of the patient's illness. Mothers felt freer talking to the social worker in a woman-to-woman relationship and could more easily ventilate their concerns with benefit. Reactive depressive reactions were not uncommon among mothers and were occasionally seen among fathers during the early period of hospitalization. Some parents required referral to a psychiatrist in their home area although most all such reactions responded well to regular visits with the hospital psychiatrist and social worker. Five mothers reacted with acute psychoses requiring short periods of treatment in a psychiatric hospital some time during their sons' hospitalizations. Each of these 5 mothers had openly displayed incestuous feelings towards their sons by such actions as the following: one mother exposed her genitals to the son on the excuse of showing him a bruise on the thigh; a second lay on top of the son in his bed while treating his facial acne; three others slept with the adolescent son. All these mothers were well aware of their incestuous strivings.

The outlook of the patient seemed definitely related to the teachability of the parents by the psychiatrist and social workers. Even among those patients who were unimproved, the parents frequently commented upon the better relationship with

their other children and the improved atmosphere of the home as a result of what they had learned.

In order to relieve suicidal trends and exhaustive states of excitement with poor appetite and sleep, 40 of the patients received ECT in addition to psychotherapy and program therapy. Insulin was used in sub-shock doses in 24 and tranquilizers were used in 15.

As the patients improved, they were moved to more free and open parts of the hospital when they could visit at home and commute to school or work. This transitional period of resuming community activities secured the rehabilitation. Therapeutic contact with patients and their relatives for prolonged periods after leaving the hospital was most helpful. The average hospital residence for the group was nine months.

Results of treatment revealed that 68 were definitely benefited by treatment, and at home, 35 of whom were considered recovered, 20 much improved and 13 improved. Twenty-eight were unimproved. One died of severe diabetes and exhausting excitement shortly after admission. Three patients died some time after leaving the hospital, two who left against advice by suicide and one who had been considered recovered was killed in an automobile accident.

The following illustrative cases are presented :

Case 1 : A 19-year-old Jewish male was admitted to the New York Hospital, Westchester Division on January 4, 1950 on voluntary minor status. For the previous two years the patient was showing increasing dependence on marijuana and alcohol, together with deteriorating social relationships. The heredity was free of mental illness. However, the father was an aggressive business man but anxious and ineffectual in the home. He suffered from bronchial asthma and had been under psychotherapy. The mother was the dominant figure, aggressive and masculine in manner. The patient was the first of two, left-handed and withdrawn as a child. The parents tended to be over-solicitous and over-protective. In school he did well scholastically but poorly socially. He had a number of athletic interests which he worked at diligently and realized considerable success. On leaving home and entering preparatory school, he was introduced to

alcohol and marijuana which resulted from strong identification with an anti-social and Bohemian group. It was during this period that he formed a close relationship with one of his contemporaries in which there was mutual masturbation associated with a fantasy of women with "penises." At the time of admission he was withdrawn, tense and expressed sensations of having a "vagina" and a "bleeding" laceration of the left hand. There were homosexual concerns and great ambivalence towards his mother. The patient had considerable intellectual insight and his attitude in regard to hospitalization was good in that he recognized he had problems and wanted help. Physical status was excellent. The patient remained 6 months in the hospital showing gradual and marked improvement. There was increasing facility and ease in his interpersonal relationships. His family was cooperative and received help in gaining understanding of the patient's needs and as a result there was an improvement in his relationship with his father. He developed numerous healthy male identifications within the hospital setting. On leaving the hospital the patient returned to college and the 10-year follow-up communication with the family revealed that he had made a complete recovery and was leading a successful life.

Case 2 : A 19-year-old male was admitted to The New York Hospital, Westchester Division on September 1, 1950 with a long history of bizarre and impulsive behavior. The patient came from German Jewish and English Protestant stock. In the paternal line there was a suicide and numerous instances of psychoses. The father was a circular manic-depressive and institutionalized during the patient's formative years. The mother, an aggressive and capable person, made every effort to give the patient an adequate opportunity for a healthy adjustment. He was an only child who, during childhood and the latency period, was neurotic, withdrawn and over-weight. In school and socially he was poorly adjusted. During adolescence he was increasingly sluggish, awkward, inadequate and persisted in a strong attachment to his mother. He was in his first year of college at the time of his hospitalization, having previously received many months of psychotherapy. Prior to his admission he became increasingly inadequate socially and his behavior was marked by withdrawal and outbursts of excitement and hostility directed towards the mother. At the time of admission he was vague, circumstantial, delusional and hallucinated. He believed that his mother was keeping his father from him. Physically he was obese with poor coordination. In the hospital he became

increasingly disorganized in his thinking and behavior with periods of excited and impulsive activity. Electro-shock therapy did not reverse the process nor did it aid him in utilizing the therapeutic environment. After 13 months of hospitalization he was transferred to a state hospital as unimproved. The 10-year follow-up revealed that he had continued hospitalized with further deterioration.

SUMMARY

The life histories of 100 young males between the ages of 14 and 19, admitted to The New York Hospital, Westchester Division from 1946 to 1956, were reviewed, with the following findings:

1. The stress of adolescence was an important precipitating factor on a background of inadequate personality adjustment dating back many years.

2. Acting out behavior included stealing, aggressive rebellion against authority, and assaultiveness particularly towards mothers. This behavior was common in both the schizophrenic and psychopathic groups which made up nine-tenths of the patients.

3. Treatment emphasized the importance of dynamic psychotherapy, as well as a well-rounded program directed towards group participation and socialization.

4. Important in treating was to provide experiences to enhance the development of strong male identification.

5. Successful outcome of treatment was related to the teachability of the parents.

6. The results of treatment were given. Two-thirds of the patients were benefited and at home.

DISCUSSION

ROBERT S. GARBER, M.D. (Belle Mead, N. J.).—The paper is intriguing and informative, but the content does not fit the

title since it is not about the treatment of troubled youth, but rather the treatment of psychotic youth, as actually demonstrated in 89 out of the 100 cases. It would be extremely interesting to know how the recovery rate reported (*i.e.*, 33 out of the 100 cases were not improved), compares with the recovery rate for adults or children of other age groups, and especially, since this group comes from a favorable socio-economic milieu and has good intellectual endowment. It is reported that school work was average in 75%; however, the school work of delinquent youths never attains 75% average in any group.

The important fact in this paper is that much of the illness seems related to separation from parents, both physically, that is, in going off to school, and emotionally, that is, in the phase of adolescence; and that the youths were most helped when their families were simultaneously provided treatment in resolving their own problems as well as in their problems of relationship with their children. This raises a basic question of prevention. The histories described are full of signs and portents of a precarious balance in adjustment for most of their lives.

Physical illness, neurological implications, accidents, personality problems, difficulty in relationships are all present. Actually, the paper points out the need for earlier detection and treatment, at a period in childhood when the parental role in the illness is both clearer and more easily reversed, when both parents and child are more accessible, rather than in adolescence.

Finally, in general, the paper reads like a good program, although not designed to treat those youths who are actually coming into conflict with society.

A COMPREHENSIVE HOSPITAL-COMMUNITY SERVICE IN A STATE HOSPITAL¹

ROBERT C. HUNT, M.D.,² ERNEST M. GRUENBERG, M.D.,³
EMANUEL HACKEN, M.D.,² AND MATTHEW HUXLEY³

This is a report of early experiences with a project to organize within the Hudson River State Hospital a comprehensive and integrated treatment service for the mentally ill in a defined population under a research design to evaluate results.

There has been set up within the hospital structure a sub-hospital—a largely complete and autonomous service unit—specifically serving Dutchess County, New York. This unit provides a broad range of treatment services which include pre-care; day hospital, night hospital and inpatient care (both acute and long term); rehabilitation services; and aftercare.

RATIONALE

The rationale of this project is as follows:

Our culture is burdened with an enormous load of disability associated with psychotic illnesses. Our present methods are not very effective in preventing or curing the illnesses, but we do now have the tools to attack the associated disability. We can relieve much of the disability which has already occurred; we can prevent its future occurrence and minimize its extent.

Our tools for preventing and reversing disability are much better than our organizational structure for bringing the tools to bear upon those that need help. Nowhere in the United States has any population been given comprehensive service which uses all the tools that we now have.

We have a tradition in our society of almost automatically hospitalizing persons with psychoses; also a tradition and current practice of not using community psychiatric facilities for the seriously ill. It sometimes appears that the richer a community is in its health, welfare and psychiatric facilities—

as in large metropolitan centers—the more difficult it is to bring these to bear to help the seriously ill person.

Hospitalization as such is among the causes of disability. This is especially true of the traditional, highly security-conscious hospital.

Even where we have a great wealth of services available and a willingness to use them, it is often difficult to get flexible continuity of care for the individual patient because the services are so independent of each other. This happens even in a single large organization; when it becomes as large as the Hudson River State Hospital it almost inevitably develops specialistic compartmentation, so that patient care tends to become fragmented.

The major hypothesis to be tested in this pilot program is that chronic hospitalization and disability can be reduced by supplying the population with a comprehensive psychiatric service based upon a small, community-oriented, open public mental hospital so organized that there is maximum continuity of care over both inpatient and outpatient phases of treatment.

LOCALE

The population served by the project resides in Dutchess County, one of the 8 counties served by the Hudson River State Hospital. It is a mixed urban-suburban and rural area of about 170,000 people. They are relatively well disposed toward their state hospital and have responded well to such innovations as the open ward system. They make liberal use of the hospital and for several years Dutchess County has had the highest admission rate of all the counties in the state, the annual rate being nearly 300 per 100,000 of population.

With the help of state aid the county supports an all-purpose psychiatric clinic. This gets more referrals for emotional and adjustment problems than it can handle, and tends to refer the more seriously ill to the

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Senior Director and Supervising Psychiatrist, Hudson River State Hospital, Poughkeepsie, N. Y.

³ Technical Staff, Milbank Memorial Fund, N. Y.

state hospital. There are no psychiatric beds or outpatient clinics in any of the general hospitals in the county. There are a few psychiatrists in private practice.

The Hudson River State Hospital is on the outskirts of the city of Poughkeepsie, the largest center of population in the county. Most of the county's residents are within half-an-hour's drive from the hospital. The hospital's patient population of 5,400 is housed in a large number of buildings spread over 1,000 acres.

The parent hospital is organized in the traditional American pattern with specialized wards and buildings for specialized functions. There is one central reception service into which all new admissions come, and specialized buildings for the infirm, the regressed, the disturbed, and diabetics or others needing special diets.

The staffing pattern is standard for New York State, with the reception service at APA standards and the continued treatment services somewhat below APA levels. There is active treatment and rehabilitation in most of the hospital and over 90% of the patients are on open wards.

There is an aftercare program which uses traveling clinics and also field social workers. Social work positions are allocated in accordance with the number of patients in extramural care which presently number about 900.

The presence of a day hospital as part of the state hospital is an almost unique asset, being one of two pilot projects set up by the Department of Mental Hygiene 4 years ago. It receives most of its referrals from the community and has won excellent community acceptance.

PROJECT

The "Dutchess County Unit" has been established in two small buildings, with a combined bed capacity of 550, which are contiguous to each other and to the medical-surgical-reception building which also houses the day hospital. Over a period of several weeks in the fall of 1959, Dutchess County patients from the continued treatment services were moved into these buildings while non-Dutchess County residents were moved out. About 85% of all Dutchess County patients have been assembled in

this unit, and it is expected that the unit will eventually care for virtually every patient from the county.

Since January 12, 1960, all Dutchess County admissions have been admitted directly to the unit. The reception service patients from the county had been moved in a few days before, together with professional staff, stenographers, files, *etc.* Since then the unit has been in operation as a virtually complete and self-contained small hospital with its own reception and intensive treatment service, a full range of long-stay patients, including the infirm and the regressed, and its own aftercare service. Close working relationships have been established between inpatient, day hospital and aftercare functions with free referral between them. The only Dutchess County patients deliberately excluded from the unit are the tubercular and those with acute medical or surgical conditions. Patients in the unit needing specialized services go across the street to the medical-surgical building for x-rays, physiotherapy, dental work, *etc.*, to avoid unnecessary duplication of facilities.

The entire unit is "open" with all wards unlocked during the day. The unit has been staffed for carrying out standard functions with standard numbers of personnel. Physicians, social workers, a psychologist, nurses and aides, have been allocated as equitably as possible on the basis of the unit's patient load and rates of admission. Every effort has been made to avoid especially favoring the unit in number or quality of staff.

What has been described up to this point is simply a new method of organizing and administering present services with nothing particularly new in the services themselves. The one new function which is in process of being added is "pre-care." This we conceive as an emergency psychiatric consultation service to the community. Those who commonly initiate moves toward hospital admission, such as physicians and police, are being encouraged to first give us a call when they have a patient for whom admission is contemplated. We will send a consultant to the home, if necessary, or see the patient in the office. We believe that this procedure can often give better service to the patient without hospitalization, by

recommending certain treatment measures to the family physician, by referral to a psychiatrist or clinic, by placement in a nursing home, or by admission for day or night hospital treatment. It is also expected that those patients who are admitted for full-time hospital care will, through this advance medical contact, have a healthier relationship with the staff and make greater use of voluntary admission procedures.

The provision of this new pre-care service will require additional staff and the creation of the new positions has been made possible by a grant from the Milbank Memorial Fund.

At this point it should be emphasized that the entire Dutchess County Service is for the mentally ill for whom hospitalization appears to be in the immediate offing. This distinction is necessary both to keep the unit from being inundated with less serious problems, as well as to define our role as not competitive with the outpatient clinic or with psychiatrists in private practice.

The success of any such venture into community-based psychiatry is in large measure dependent upon community understanding and involvement. Beginning with the earliest planning stages a year before the opening, conferences were held with various community leaders. There have been many conversations with individuals and groups, and several open meetings to clarify issues. Especially helpful cooperation has been given by the county's Community Mental Health Board, and by an *ad hoc* committee of the County Medical Society set up to study the plan.

RESEARCH

It is assumed that this new organization of psychiatric care is better than that we now have. We are sure that staff, patients, relatives and community agencies prefer it; no research is needed to tell us that.

We also believe that patients will become permanently hospitalized less often, will deteriorate less frequently and severely, and will maintain their social functioning at a higher level. To know whether or not the new program will produce these changes requires systematic data-gathering and analysis.

As far as we have been able to determine,

no system or organization of psychiatric services has been sufficiently well studied for us to be confident that it benefits patients more than another system. It is our intent to try to answer this question. Responsibility for these studies is assumed by the technical staff of the Milbank Memorial Fund. This staff has re-formulated the statements about the ways in which the course of psychotic illnesses may be improved by the new unit as follows.

Hypotheses to be tested :

1. That there will be fewer instances of long-stay hospitalization for psychosis than there would have been without the unit.

2. That episodes of psychotic decompensation in chronic psychoses will be less severe, and will be less frequently associated with deterioration and social disability.

3. That more Dutchess County residents who were on long-stay services in the hospital in October 1959 will be rehabilitated to the extent of being able to leave the hospital.

4. That even those who were long-stay patients and who do not leave the hospital will come to function at a higher level and be less deteriorated than if the unit had not been established.

These 4 hypotheses are in process of being tested. We are trying to think out logically and systematically what evidence is needed to test each of them. There are not many ready-made investigative tools available.

Because space does not permit detailed description of the entire research design, we will illustrate only the approach to the first hypothesis. It is necessary to specify both what is meant by "long-stay" hospitalization and the measurements of its occurrence, so that we can determine whether or not it is becoming less common. The specified measure of "long-stay" hospitalization is *continuous* hospitalization for a number of months. Leaving the hospital on convalescent status is regarded as leaving the hospital and not as staying in the hospital. It is not clear how many months of continuous hospitalization should be regarded as "long"; it may lie somewhere between 4 and 20. It is well known that the frequency of shorter periods of hospitalization

does not determine the frequency of long-term hospitalizations ; the number of such short-term admissions and readmissions may even rise as a result of the unit's activities.

One measure which has been selected is the frequency with which individuals in the county experience their first long stay. This number has been determined for each of the past 10 years to get a picture of its size and stability from year to year. These frequencies are presented in Graph 1.

Each line reflects a different definition of "long stay." If 4 months is regarded as

a long-stay admission, the top line shows the number of people from Dutchess County who have completed a stay of 4 continuous months for the first time in their lives, for each of the years 1950-1959. The bottom line shows the number if 20 months is regarded as "long stay." The curves in between show what is found if we use definitions of long-stay intermediate between 4 and 20 months. The arrows indicate the direction these curves will have to take to justify a conclusion that the unit has made the expected difference.

GRAPH 1
NUMBER OF DUTCHESS COUNTY PATIENTS EXPERIENCING SPECIFIED DURATION OF CONTINUOUS HOSPITALIZATION FOR THE FIRST TIME, BY YEAR

Similar curves will also be made for residents of other counties in the hospital's service district. Likewise, for comparison, these curves will be made for some counties near other mental hospitals. If these others fail to show a decline and if Dutchess County does (assuming no marked changes in population), we will be able to draw some conclusions. While it cannot be predicted with confidence that clean-cut findings will emerge, at least a forward step will have been taken toward better evaluation of changes in the organization of psychiatric care.

The methods being used to test the other 3 hypotheses will be reported elsewhere.

RESULTS

It is much too early to draw conclusions from the brief experience to date, but a few observations seem worthy of mention. The most obvious and striking immediate change is in staff attitudes, with an almost universal excitement and intense dedication to their work. Some might regard this as a contaminating artifact in the project but we consider it a *predicted* result of the administrative decision, and a verification of our assumption that a better organizational structure will produce better staff performance. Without doubt, the staff enthusiasm is in part due to pride in having been chosen for the project, but we believe that the structure itself evokes emotional identification with the small unit which is peculiarly their own. On their own initiative the staff have instituted several new treatment and rehabilitation activities; they are trying to do so much that they complain of not having enough hours or enough hands to do all they want to. All of the staff are delighted with the ease and flexibility of decision-making in the small unit; communication is immediate and face-to-face without the lengthy chain of command which can be so frustrating in a larger organization.

The unit is too small to permit classifying the patients into homogeneous ward groupings. This obstacle to traditional practice reinforces our conviction that it is better for

the patients if they are in heterogeneous groupings. Two infirm wards, one male and one female, are the only wards in the unit which house just one type of patient. There are no reception wards as such: new patients are admitted to any one of the 6 wards all of which also have long-stay patients. Patients who were transferred to the unit from homogeneous regressed wards have been scattered through all wards. With rare exceptions, these regressed patients have responded quickly by becoming more alert and tidy. There is a steady trickle of long-stay patients improving and leaving the hospital; in the first three months some 30 patients who had been in hospital over a year were released, thus freeing beds for remaining Dutchess County patients to be moved in from other parts of the hospital. The early trend is in the direction of a reduced hospital population, although the number of admissions is higher than ever.

There appears to be a significant increase in voluntary admissions; in the first 3 months half the admissions were voluntary. There is also a steady increase in self-referrals to the day hospital, and the success of this service is creating a heavy demand for an evening hospital which will give active treatment during the evening hours. This latter service is not yet in being, but is planned for a later date when staff may be available.

SUMMARY

A newly organized, 550 bed hospital, rendering comprehensive, psychiatric care (day hospital, night hospital, post-hospital, pre-hospital and consultation) to residents of Dutchess County, N. Y., has been created within the 5,400 bed Hudson River State Hospital. This is designed to give continuity through close integration of a wide variety of treatment services. Early experiences with the project are reported.

Evaluation studies are testing the hypothesis that this type of service will reduce the frequency and severity of disability associated with mental illness, as measured by rates of admission, institutionalization, and deterioration.

PROBLEMS IN THE CORRELATION OF PSYCHOPATHOLOGY WITH ELECTROENCEPHALOGRAPHIC ABNORMALITIES¹

RONALD R. KOEGLER, M.D., EDWARD G. COLBERT, M.D.,
AND RICHARD D. WALTER, M.D.²

INTRODUCTION

The application of computer techniques to the examination of the electroencephalogram has evoked a great deal of interest. This interest results from the desire to further quantify, to dissect features in the EEG that may not be apparent to simple visual inspection. In the jargon of communication engineering: there is a great deal of "noise" in the electroencephalogram. Potential change appears in a pseudo-sinusoidal fashion that must be treated currently as "noise" because no meaningful signal appears to have been transmitted. Traditional visual inspection has contributed information that is quite helpful in a clinical setting, but it is only a rough summary of many potential "bits" of information.

Frequency analysis in various forms has been available for nearly 15 years. The EEG can be converted into a histogram based on the frequencies but in spite of the availability of such quantifiable data, few reports have appeared correlating frequency analysis with psychological data. Some of the major disadvantages are the loss of phase relationship, the inability to analyze more than one channel at a time, and the long time periods required for the analyses.

A technique which is more recent and is rapidly gaining in popularity is correlation technique, both auto and cross. A complex series of electrical changes making up the electroencephalogram is electrically correlated with itself displaced in time, or to another known and simpler series of wave forms. These techniques are very sensitive for the detection of rhythmical repetitive events marked by ongoing activity—such as evoked responses from a flashing light—but do not offer as much toward the further analysis of non-repetitive electrical activity.

Up to now, attempts to correlate EEG abnormalities with psychiatric syndromes have resulted in a notable lack of success and a great deal of confusion due to the many conflicting reports. At first it seemed to us that the problem lay in the lack of refinement in EEG interpretation based on visual inspection, and that once computer techniques became available, the relationship between psychopathology and the electrical activity of the brain would begin to manifest itself.

Recently, however, we have begun to realize that the problem lay not only in the interpretation of the EEG, but also in the evaluation of psychopathology.

For example, we recently attempted to discover if there was any characteristic behavioral or emotional pattern associated with 14 and 6 per second positive spiking in the EEG. It has been reported that children with such an abnormality, while often giving the appearance of model children, are subject to periods of impulsive aggression and may even commit murder. Our study(1), which was carefully controlled, failed to confirm the clinical observations made by others. We found no difference in aggression and impulsive behavior between these children and the control groups. While we felt that we had done as good a job as was possible with the research techniques available, certain defects in these techniques became evident.

In spite of these difficulties, we do feel that such studies should be attempted. Uncontrolled studies are almost completely worthless. We thoroughly deplore the publication of studies which state that "abnormal EEGs are found in such-and-such a percentage of disturbed children or schizophrenics or what-have-you." Blind control studies are essential, with criteria for EEG abnormality and behavioral abnormality thoroughly described.

Specifically, in terms of the 14 and 6 abnormality, almost all the work published

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Departments of Psychiatry and Medicine (Neurology), UCLA Medical Center, Los Angeles 24, Calif.

on this subject has reached premature conclusions regarding the significance of 14 and 6 per second positive spiking. These reports have been characterized by absence of control groups or poorly conceived controls, with vague descriptions of the criteria for EEG abnormality and practically no understanding of the complexities of behavior.

Perhaps one reason that investigators have shied away from more careful studies is the difficulty in evaluating and measuring behavior. This is the problem we ran into with the children in our study. We examined these patients by thorough psychiatric, psychological, and neurological examinations. Our problems arose when we attempted to quantify such factors as aggression, hostility, and impulsiveness. Accurate measures were necessary in order to compare the children who had the 14 and 6 per second spiking with the control groups. Similar difficulties arose in all areas—psychiatric, psychological, and neurological.

PROBLEMS IN PSYCHIATRIC EVALUATION

It became evident to us that it is not possible to quantify personality characteristics by means of psychiatric evaluation, except in a very gross way. For example, it might be stated that an emotionally disturbed boy "had a problem handling his hostility." This phrase can be applied to many disturbed persons, regardless of cause. When you are attempting to distinguish differences in the pattern of aggression among disturbed children, such a gross description is extremely inadequate and frustrating.

This problem is not unique to this type of study; the search for specificity has been unsuccessful in all areas of psychiatry. In evaluating acute schizophrenics, for example, it was formerly thought that the psychotic verbalizations were directly related to the etiology. When a schizophrenic heard voices accusing him of wanting to kill his wife it was assumed that his "problem with hostility" was significant in causing the psychotic break. We now realize that the things which schizophrenics are accused of by their voices are extremely stereotyped. This can be useful in psychotherapy; an omnipotent role can be assumed almost immediately with a new patient by describing

the content of his hallucinations to him, much to the patient's amazement. The point is that *all* disturbed patients are bothered by hostile impulses, as well as other types of emotions, and the disturbed children in our study were also losing control of these impulses.

We were trying to find something unique about a particular group of children with a certain EEG abnormality, and were suspicious on clinical grounds that they were characterized by some peculiar, impulsive expression of aggression. However, when mixed in with a group of other disturbed children in a blind examination all groups had high percentages of children with "aggression problems"; attempts to quantify the aggression, except in a very rough way, revealed only our helplessness. Differences in quality were equally difficult to discover.

Since we have this difficulty with such a gross EEG abnormality, how will we handle a refined rhythm visible on the computer?

PROBLEMS WITH ANAMNESTIC MATERIAL AND PSYCHOLOGICAL TESTS

One would expect an emotionally disturbed or aggressive child to be diagnosed on the basis of clinical history, but the problem of further differentiation among types of aggression, so as to delineate an organically driven variety, is extremely difficult. One soon realizes that most symptoms can accompany either emotional or organic pathology. Retardation, temper tantrums, bed-wettings cannot be assigned to a single cause.

Similar difficulties apply to the use of data from psychological tests. Here again the problems of the child in dealing with aggression were revealed, but differentiating subtle differences in the handling of aggression between disturbed children proved more difficult. This is true in projective tests, such as the Rorschach and TAT, as well as on the MMPI.

PROBLEMS IN NEUROLOGICAL EXAMINATION

When the neurological findings are quite gross it is apparent that there is good correlation to other evidence of brain damage. There can be little equivocation concerning the significance of the paretic limb, an ex-

tensor plantar response, or an intention tremor.

It is more difficult and uncertain to evaluate the "soft" neurological signs—a slight clumsiness, minimal changes in the sensory examination, or a subtle reflex asymmetry. Brain damage removed to some degree from the main motor or sensory pathways notoriously may be difficult to detect and will be missed if the "hard" neurological signs alone are looked for. What is obviously needed is a great extension and perhaps quantification of the subtle, minimal, and more elusive findings.

DISCUSSION

These problems are not unique. However, they emphasize the primitiveness of the methods we have available to study the complex human psyche. This is not to belittle the efforts necessary to reach the present level, but rather to emphasize the work that needs to be done.

Often we become carried away by scientific progress which promises to make available all sorts of new information. Hidden EEG patterns which now are discernible have meaning only in terms of human behavior. Attempting correlations with such gross entities as psychosis, schizophrenia, neurosis, or behavior problem will lead to very little which is new or enlightening. Until the "group of schizophrenias" is broken down into meaningful subdivisions, for example, most correlations will be lost. Even a basic separation into schizophrenic reactions and "grown-up" childhood schizophrenics would be helpful, and also possible with our present knowledge.

In terms of studies dealing with attempted correlations between behavior and EEG abnormalities, it is obvious that the significant items are not grossly visible. It is only with some ingenuity and considerable effort that one can hope to pick up more subtle differences.

As an example of a currently useful technique, items which are not significant enough in themselves can be grouped with

other items to form symptom or behavior profiles. In the study described earlier we formulated and used such scales as "aggressive behavior," "organic symptomatology," "emotional symptomatology," and "disturbed mother syndrome." Such scales can be formed with pertinent items from psychiatric, psychological, and neurological examinations, often yielding meanings which could not be seen in the single items.

It is only through further development of more subtle measures that studies in this area can become meaningful. Better methods of quantifying psychiatric and psychological examinations are needed. The development of computer techniques points up the inadequacies of our methods for evaluating behavior and emotional content. It should spur us to meaningful research in this area.

SUMMARY

1. Frequency analysis has been available for nearly 15 years, but its inherent disadvantages have limited its use in correlating the EEG with clinical data. Auto-correlation and cross-correlation techniques are more recent and hold considerable promise.

2. The use of these techniques will add little to our present knowledge unless we also improve our methods of quantifying behavior and psychopathology.

3. Most studies of EEG abnormalities in psychiatric syndromes have little value because of lack of controls and poorly-defined EEG and behavioral criteria. This has been true in studies of the significance of 14 and 6 per second positive spiking.

4. Research should be directed toward developing techniques which will enable us to quantify behavior and emotional impulses in a more accurate and scientific manner.

THE EFFECT OF PHENOTHAZINES ON THE INTERACTIONAL BEHAVIOR OF SCHIZOPHRENIC PATIENTS¹

LUCIE A. WOOD, Ph.D., AMY MIKLOWITZ, B.A., ELIOT D. CHAPPLE, Ph.D.,
MARTHA F. CHAPPLE, B.A., NATHAN S. KLINE, M.D.,
AND JOHN C. SAUNDERS, M.D.²

Evaluation of behavioral change in schizophrenics is usually dependent on either subjective judgments of the physician or on the interpretation of verbal material obtained as a reaction to more systematic procedures. To obtain precise information about one aspect of the patients' behavior, we employed the interaction chronograph procedure which provided measurements of the duration and frequency of action. In our formalized interview we obtained laboratory data which enable us to predict the patterns of behavior participated in by the individual in other interactional situations. We hypothesize that upon further analyses of the data, patterns of interaction will become evident which may ultimately prove useful in classifying human behavior. This investigation was based on the hypothesis that interactional patterns would be modified by phrenotropic drugs and this would provide an objective method to evaluate clinical response to psychopharmacological therapy.

By introducing measurements of activity, aggressiveness, initiative, dominance and other factors as defined in the interaction chronograph method we can make specific quantitative comparisons between patients' response to phrenotropic drugs. This paper presents data on the effects of phenothiazines in a group of hospitalized psychotic patients. We have selected a group showing a wide range of activity levels in order to obtain a sample of the hospital population. Through this study, we expect to establish the effects of these drugs on behavior and to demonstrate any uniformities which may be present.

PROCEDURE

Twenty-seven patients were tested by the standardized interaction chronograph

(stress) interview. The timing of their responses was recorded by an unseen observer using a portable interaction recorder. The results were tabulated on the interaction chronograph computer and further analysis was made and is presented, in part, in this report.

The patients were selected from various wards at Rockland State Hospital. They included 12 chronic female patients, 3 acute females, 4 chronic male patients and 8 acute males. None of the patients had any complicating physical disorders nor were any mentally defective.

The standardized interview used has been described in detail elsewhere(1). The only significant difference in the procedure used in this study is that combinations of variables were used to obtain average activity and average maladjustment figures. An initial interview was given to the patients before they received drugs. A second interview occurred between 4 and 6 weeks after the initial interview.

In that paper(1) we described the measurements of action and silence (inaction) which represent basic variables from an operational point of view. To make our measurements comparable with work on animals and earlier publications on interaction(2, 3, 4, 5) we have used the average net difference between action and silences during the base period of the interview. Our hypothesis is that the individual tries to achieve a balance between periods when he cannot or does not talk because the other person is doing so, as against those periods when he is playing the active role. Similarly, we have used what we term an average net maladjustment score. This is made up of the net difference between the length of a person's interruptions, counted as positive, and the length of his latencies to respond, counted as negative. Thus, if the average maladjustment is positive, there were longer interruptions than failures to respond; if

¹ This study was supported in part by Public Health Service Grant MY 2350.

² Research Facility, Rockland State Hospital, Orangeburg, N. Y.

negative, there were longer latencies. This is based on a second hypothesis: that adjustment is analogous to a servo process and that over-long hesitations in one interval are balanced by a speeding up and the possibility of interruption in the next.

The 27 schizophrenic patients were given one of the phenothiazines: Trilafon (perphenazine), Compazine (prochlorperazine) or Thorazine (chlorpromazine) with the dosage titrated to alleviate the individuals' presenting symptoms. Our experience with the administration of these phrenotropic drugs in man indicates that they have three major types of activity: (a) sedative, (b) increased motor and (c) antipsychotic. The antipsychotic effect is demonstrated by definite behavioral improvement with a significant reduction in aggressive behavior, lessened emotional tension, a decrease in hallucinations and delusions and some improvement in affect.

RESULTS

Table 1 presents the data on the 27 patients and shows that the range of average activity rate in the initial interview was from 5.9 hundredths of a minute (3.5 seconds) to an extreme high of 1112.5 (11.1 minutes). Data indicate that in this series, there are no significant differences in the activity range between men and women. It should be noted also that this series was limited to patients whose base activity rate in the first interview was not negative, that is, the durations of the actions were longer than their silences. Only a relatively small number of patients with negative activity were available and they will be mentioned in the discussion.

Each patient shows a decrease in activity level from the first to the second interview associated with the administration of a phenothiazine preparation. The drop in activity is significant by *t*-test at the .01 level. It should be emphasized that no significant changes on reinterviewing of controls are encountered as Saslow and Matarazzo have demonstrated in a number of studies(6).

The most interesting finding, however, is that the amount of drop from the first to the second interview, given in the third column, is a function of the level of activity

$t = 2.872$

Significant at .01 level.

Correlation between Activity Level in Interview 1 and amount of drop after tranquilizer.

$r = -.987$

shown in the initial interview. Calculation of the coefficient of correlation yields a Pearsonian $r = -.987$.

In a series of 27 a Pearsonian r of this magnitude is highly significant at the .01 level. In other words, the results from this series confirm the clinical observations that the greater the activity of the patient, that is, the more hyperactive he is, the greater the effect on his activity as a result of the administration of phenothiazines. The male patient with the highest activity, indicating that he talked on the average of over 11 minutes in a response, dropped during

medication to an average of slightly under 2 minutes. The low activity patients show very minor drops. Figure 1 presents these results in graphic form to illustrate the nature of the correlation.

Table 2 presents the data on the same patients for average net maladjustment. Here the results are not as clear since the significant difference between men and women is in association with the quantitative character of the maladjustment. The 15 women with two exceptions, all show a

drop in adjustment from the first interview and the t-test is significant at the .01 level. On the other hand, the men show no systematic change in their average maladjustment scores from the first interview to the second and if the t-test were used the change would not be significant.

Examination of the figures for the 5 men and 13 women whose net maladjustment is positive (that is, where the durations of interruptions are significantly greater than the latencies of response), indicates a

drop occurred in 4 of the 5 men and 12 of the 13 women. A larger series and a separation of interruptions from latencies is necessary to determine whether and to what degree differential effects are produced by the phenothiazines on each variable in the components of maladjustment.

It is important to emphasize that the data on activity and maladjustment do not parallel one another but may operate independently. Therefore, one cannot assume that activity level is decisive. For example, male patient Ni. with a 334 activity shows a net maladjustment of -8.5 and although his activity drops significantly in the second interview he becomes much more interruptive and far less latent. On the other

hand, female patient Ry. with an activity of 176 drops substantially in the second interview and also shows a lower value in net maladjustment of 2.0.

DISCUSSION

Much of the work done to evaluate drugs in the laboratory phase of their development involves the measurement of locomotor activity in laboratory animals, usually the rat. Irwin(7) and his associates have shown, using perphenazine, that the locomotor activity of the hyperactive rat is depressed to a considerably greater degree than that of the hypoactive animal. They also found that there were no significant differences between female and male rats in their response to the drug, though in their sample of the species, there was a greater frequency of highly active animals among the female population.

Irwin also emphasizes the importance of knowing the base activity level of the animal studied and points out that evaluation of the effects of drugs can be strongly influenced by the accidental selection of hypo- or hyperactive animals. Interpretation of interaction chronograph results on humans also emphasizes this point. Consequently we need to know the activity level of the individual patient as well as his level of maladjustment (and other variables to be discussed in future publications) before we can properly evaluate the effects of the phenotropic drugs. The higher reliability of the interaction chronograph procedure using the standardized interview, as Saslow and his associates have demonstrated, makes the method of interaction an extremely useful one for psychopharmacological studies(6).

Comparison of experimental animal and human measurements, indicates that the locomotor patterns of activity in the animal have possible analogues in the communicative interactional patterns of the human. In general, one may assume that the two types of activity have physiological mechanisms in common and therefore more precise correlations between animal and human studies would appear possible.

There were a small number of patients placed on phenothiazines whose net activity level was negative. In some of these pa-

tients, phenothiazines increased rather than decreased the net activity. This was probably due to a decrease in silences with little or no change in the relatively brief duration of actions. We do not, however, have a large enough series to come to any definite conclusions; rather, the evidence from this series of patients with activity on the positive side strongly suggests that the duration of actions is what is affected and that the higher the action the greater the drop. Periods of silence (inaction) as well as pronounced latencies appear to be affected in ways which we do not as yet understand. It may be possible to differentiate the behavioral activity of phenothiazines as well as other psychopharmacological agents by the interaction chronograph technique.

CONCLUSION

We have demonstrated that the interaction chronograph interview provides an objective method for determining the behavioral effect of the phenothiazines in schizophrenic patients. This method then contributes in part to the solution of one of the major problems of psychiatry, the evaluation of the nature, direction, and degree of change following therapy. The administration of phenothiazines has been shown to affect specific variables, measurable by the interaction chronograph; the identifiable changes in interaction have been found to correlate with clinical evaluation. The response of the 27 schizophrenic patients to these drugs shows that there is

a significantly high correlation between activity levels and drug effects.

Average net maladjustment drops significantly in the females but not in the males. This appears to be dependent upon a high positive maladjustment (aggressiveness) rather than a sex difference, since most of the males in the series predominantly show marked latency of response. The few males with high positive maladjustment also show drops comparable to that of the females.

The effect of phenothiazines on the interactional behavior of schizophrenic patients has been shown by this procedure. Further analysis of the data suggests that other behavioral criteria will become evident.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

THE RELATION OF ATTITUDE TOWARD MEDICATION TO TREATMENT OUTCOMES IN CHEMOTHERAPY¹

DONALD R. GORHAM, PH.D.,² AND LEWIS J. SHERMAN, PH.D.³

Several recent articles have emphasized that a patient's response to medication is due not only to the purely pharmacological properties of the drug itself (1, 3, 7) but, rather, is a complex function of the interaction between 3 classes of variables: drug, situation, and person (13). There is a growing body of evidence that the personality of the drug recipient and the total social setting in which the drug is administered are important determinants of a patient's response to chemotherapy (5, 9, 10, 11, 12).

The purpose of this study was to investigate the influence of one of these non-drug determinants, viz., the relationship between a patient's attitude toward medication and his response to a drug. It was hypothesized that patients holding positive, favorable, and enthusiastic attitudes toward drugs would show a greater response than patients not so favorably disposed to this mode of treatment. Indirect support for this hypothesis has been demonstrated by those investigators who found that physicians favoring drug therapy had a greater degree of success than those opposing the use of drugs in treating mental illness (4, 6).

Sherman (14) has recently described the construction of a projective sentence-completion test to measure patient attitudes toward medication. This version of the test is still preferred for the intensive study of individual subjects since it furnishes a rich vein of clinical material. However, for the

large scale research project reported here, a briefer multiple-choice form was developed which yields essentially similar information and is objectively scorable. The 4 completing statements for the stem of each item consist of one which expresses a positive attitude toward the benefits of taking medicine, one a negative attitude, one a neutral attitude and one a statement concerning a side effect. The following are some examples of the test items and their scoring categories:

1. Since I started taking medication
 - A. I have been getting pills. (Neutral attitude)
 - B. I feel sleepy. (Side effect)
 - C. I feel worse. (Negative attitude)
 - D. I feel better. (Positive attitude)
2. I take medication because
 - A. I am forced to take it. (Negative attitude)
 - B. I want to get well. (Positive attitude)
 - C. I want to increase weight. (Side effect)
 - D. This is a hospital. (Neutral attitude)

In scoring, the positive choices were assigned 3 points; the neutral and side effects choices, 2 points and the negative choices, 1 point. A pilot study conducted at Waco and Perry Point VA Hospitals indicated that the scale was within the comprehension of chronic schizophrenic patients and presented no difficulties in administration. About 80% of the 76 patients in the pilot study were able to complete the scale; test-retest reliability on a sample of 45 patients proved to be .79.

The test was completed by 369 patients which was 80% of the number included in Project IV. A factor analysis of the 14 items

¹ Part of Project IV of the Veterans Administration Cooperative Studies of Chemotherapy in Psychiatry (2). Portions of this paper were presented at the Veterans Administration Research Conference on Cooperative Studies in Psychiatry, Cincinnati, June 6, 1960.

² VA Central NP Research Laboratory, Perry Point, Md.

³ VA Hospital, Brockton, Mass.

showed that most of the variance was taken out by the first centroid factor. Each of the 14 items had a high correlation with this factor, with 12 co-efficients exceeding .90. For all practical purposes, then, the total score of the scale is a valid single index of the patient's belief that medication will improve his psychiatric condition.

In the main study, psychiatric interviews using the Inpatient Multidimensional Psychiatric Scale (IMPS) (8) and ward observations recorded in the Psychotic Reaction Profile (PRP) (9) had been gathered at the beginning and end of the 20 week treatment period. These scales had been keyed to yield the following 17 symptom measures :

IMPS; excitement, paranoid projection, disorientation, agitated depression, perceptual disorganization, motor disturbance, hostile belligerence, withdrawal, grandiose expansiveness, conceptual disorganization.

PRP; thinking, disorganization, withdrawal, paranoid belligerence, agitated depression, resistiveness, dominance, activity level.

RESULTS

The hypothesis that the attitude of patients toward their treatment is related to treatment response as measured by these 17 criteria was tested for the patients in Project IV. When all patients were considered, without taking into account differential drug treatment, there were no statistically significant relationships. In other words, for these 369 patients, changes in symptom areas were not related to patient belief in the efficacy of medication.

When the patients were considered by drug groups one relationship statistically significant at the .01 level and three at the .05 level appeared. Since the 17 factors were analyzed separately for 5 drug groups making a total of 85 statistical tests, these 4 significant relationships are about what might be expected by chance. It should be noted, however, that these 4 relationships were all in the expected direction; i.e., symptom relief was related to positive attitude toward medication.

The relationships between attitude toward medication and pre-treatment symptom measures were found to be statistically

significant (.01 level) for 6 of the criteria: IMPS; paranoid projection, perceptual disorganization, hostile belligerence and conceptual disorganization, PRP; paranoid belligerence and resistiveness. This cluster of factors which approximates the paranoid syndrome of symptomatology suggests that the more paranoid the patient, the less faith he has that he might be helped by medication.

SUMMARY

An Attitude Toward Medication Scale was administered before and after treatment to 369 patients in a large-scale chemotherapy study. The hypothesis that the attitude of patients toward medication has an important bearing on treatment effect was not upheld with this population of chronic, apathetic schizophrenics. Medication attitude, however, was significantly related to a cluster of symptoms that tend to characterize paranoid schizophrenics indicating that the more paranoid the patient, the less faith he had that he might be helped by medication.

THIORIDAZINE HYDROCHLORIDE¹ IN THE TREATMENT OF BEHAVIOR DISORDERS IN EPILEPTICS

PABLO M. PAUIG, M.D., MARIE A. DELUCA, M.D.,
AND ROGER G. OSTERHELD, M.D.²

The treatment of behavior disorders in epileptics constitutes a difficult problem, especially in institutionalized patients. These disorders include hyperactivity, aggressiveness, irritability, stubbornness, temper tantrums and destructiveness. Mental deficiency often accompanies or follows epilepsy and represents a significant feature of the behavior pattern evidenced by these cases.

Preliminary observations in a small group of patients indicated that Mellaril exerted a beneficial effect on behavior disorders and prompted us to undertake the full-scale evaluation reported here. For this purpose, 100 patients were randomly selected from the adult and pediatric services of this hospital for epileptics and treated with Mellaril for periods ranging from 3 to 10 months.

Dosage was titrated as much as possible in each case, starting with 10 mg. daily in children and 25-50 mg. daily in adults, and increasing by similar increments until optimum effect was obtained. Maximum dosage was 150 mg. daily in children and 600 mg. daily in adults. Blood counts were performed before, during and at the close of this study. Periodic examinations were made to detect any untoward reactions, while disturbances and seizures were recorded on each patient's chart as they occurred.

RESULTS

Analysis of the patient's behavior patterns at the conclusion of the study revealed the following: markedly improved, 61; moderately improved, 28; no change, 11.

¹ Mellaril, Sandoz Pharmaceuticals.

² Respectively: Staff Psychiatrist, Clinical Director, and Superintendent, Monson State Hospital, Palmer, Mass.

Criteria for assessment included ward behavior, number and degree of temper tantrums and manageability. Those rated markedly improved became generally more sociable, friendly, easily manageable and free from destructive behavior patterns. A rating of moderate improvement was applied to those showing a reduction in incidence and degree of behavior disorders, but not complete control thereof.

It became evident during the course of the study that convulsive seizures were also being influenced and an analysis of the patient charts showed:

No seizures after the institution of Mellaril therapy, 23 patients

Decrease in number of seizures, 41 patients

No change in number of seizures, 20 patients

No seizures before and during administration of Mellaril, 16 patients

Increase in number of seizures, 0 patients

Total, 100 patients

No alteration in blood counts, red, white and differential, was encountered in any patient in this series, nor was there any evidence of jaundice, extrapyramidal symptoms, photosensitivity or dermatitis.

DISCUSSION

Zarling and Hogan's(1) report that Mellaril is effective in the treatment of behavior disorders led to the study described here. Considerable improvement in behavior was obtained with Mellaril, but equally significant was the increased control of epileptic seizures. This was unexpected in the light of reports(2, 3) that other phenothiazines appeared to have an epileptogenic tendency. Rather, our study revealed that seizures did in fact decline as behavior disorder

ders were controlled. Since Mellaril does not itself demonstrate anticonvulsant activity (4) its effect on seizures must be ascribed to the reduction of hyperactivity and emotional disturbances which serve to trigger convulsive attacks. Anticonvulsant medication was maintained throughout and must be considered indispensable in the treatment program for such patients.

SUMMARY

Mellaril was evaluated as treatment of behavior disorders in 100 epileptic patients in a study extending over a period of 3 to 10 months. Marked improvement in behavior was achieved in 61 patients and moderate improvement in another 28 patients.

An unexpected consequence was the concomitant reduction in epileptic seizures, 64 of the 100 patients exhibiting no or fewer convulsive attacks during the administration of Mellaril. This provides tacit evidence that control of the emotional factors can exert a beneficial effect on seizures. However, it is emphasized that specific anticonvulsant medication was continued throughout the course of this study.

Repeat examinations failed to reveal any signs of jaundice, photosensitivity, blood

dyscrasia, extrapyramidal stimulation, or dermatitis.

CONCLUSION

This study has shown that Mellaril is an effective agent in the treatment of behavior disorders in epileptic patients and that relief of these also results in a reduction in convulsive seizures. Its usefulness was enhanced by the absence of untoward reactions within the dose ranges which were used in this evaluation. These findings suggest more extensive investigation to determine its potential in the total rehabilitation of epileptics.

METHOXYDONE (AHR-233) IN HOSPITALIZED NON-PSYCHOTIC PATIENTS

LEO SHATIN, Ph.D.,¹ AND THOMAS H. GILMORE, M.D.²

A double blind study³ of 5-(o-methoxyphenoxymethyl)-2-oxazolidone, AHR-233 and inert placebo was conducted to study the former's alleviation of signs and symptoms in non-psychotic hospitalized psychiatric patients. Methoxydone is a muscle relaxant which may have selective action for states of marked tension, anxiety and agita-

tion with depression, in hospitalized mental patients with chronic or acute psychoses.⁴

All male psychiatric patients admitted to a general hospital over a 6-month period who met the following criteria were entered into this investigation: age under 55, not psychotic, no organic brain syndrome, intelligence high dull normal or better, and medically cleared for study. Experimental (SS) and placebo (KK) groups were initially matched patient for patient according to the degree of anxiety as measured by the Taylor Manifest Anxiety Scale. Two evaluation instruments were used. One, the aforementioned Manifest Anxiety Scale, was a questionnaire which reflected somatic, behavioral, and/or psychic symptoms of anxiety as perceived by the patient within him-

⁴ Denber, H. C. B. : *Am. J. Psychiat.*, 115 : 360, Oct. 1958.

self. The second, an observational Clinical Psychiatric Rating Scale amenable to quantification, was completed by the patient's hospital psychiatrist from his knowledge of the patient as gained through interview, observation, and discussion with ward personnel. On this rating scale the patient was scored 1 (Absent), 2 (Minimal), 3 (Moderate), 4 (Strong), or 5 (Marked) for each of the following: Anxiety and/or Tension, Depression, Sleep Disturbances, Excitability and/or Emotional Instability, Suspicious-Sensitive, Hostility, Overinhibited-Rigid, and Inability to Concentrate. These part scores were summated to give an over-all total pathology score. The items were initially selected as having some relationship to the kind of symptom or sign which methoxydone might be expected to alleviate.

Evaluations on the Manifest Anxiety Scale and the Clinical Psychiatric Ratings were made pre-drug (1-2 days before medication was started); 3 weeks after medication was begun; 6 weeks after medication was begun, at which point it was discontinued; and 2 weeks following discontinuation. Methoxydone dosage was 400 mg. t.i.d.

Placebo was administered in similar form and frequencies. No toxicity signs were observed for methoxydone, nor were there any side reactions later traceable to that drug. The technique of paired matchings was employed for the statistical analysis of results on each instrument. The results for the Manifest Anxiety Scale are based upon sample size $N=14$ in each of the two matched groups SS and KK, while the results for the Clinical Psychiatric Rating Scale are based upon $N=16$ for each of the two matched patient groups.

Results revealed similar outcomes for the experimental and control groups on the Manifest Anxiety Scale scores and on the Clinical Psychiatric Rating Scale total pathology scores. Both groups improved through hospitalization *per se*. But there was no evidence that methoxydone speeded recovery or alleviated signs or symptoms any more effectively than did placebo. A separate analysis made for the "Anxiety" part-score of the Clinical Psychiatric Rating Scale gave no better outcome. Hence, for this non-psychotic sample under these conditions and within these dosage limits methoxydone proved to be ineffective.

HYPOTENSION ASSOCIATED WITH THIORIDAZINE HCl

DAVID W. SWANSON, M.D.¹

Hypotension has been an undesirable effect in the phenothiazines. This has ranged in magnitude from circulatory collapse to mild complaints of faintness.

Thioridazine HCl (Mellaril) has been reported to be superior because of the low incidence of side effects and toxicity (1, 2). The following case reports indicate hypotension is an exception that must be considered in this therapy.

Case No. 1: This 30-year-old normotensive man had received chlorpromazine, 600 mgm. daily, in January without any side effects. He had no positive allergic history. In March he was begun on thioridazine 50 mgm. t.i.d. One hour after the second dose he staggered into the hall appearing pale and fell to the floor

striking his head. His blood pressure was 88/50, pulse—60 and his arms appeared "blotchy." A hypersensitivity reaction was considered. Twelve hours later upon assuming the upright position his blood pressure was 84/56, the pulse thready and return to bed was necessary. One week later he began receiving prochlorperazine which was tolerated satisfactorily.

Case No. 2: A 25-year-old woman with a blood pressure of 120/70 on admission showed a diminished pressure on thioridazine 25 mgm. q.i.d. (90/60). After 24 hours on 50 mgm. q.i.d. she complained of being weak, dizzy, nauseated and faint. At that time the blood pressure was 60/0 and the pulse 60. This patient demonstrated objective hypotension on other phenothiazines also.

Case No. 3: A 19-year-old girl received thioridazine which was gradually increased to 100 mgm. q.i.d. and then began complaining of

¹ Illinois State Psychiatric Institute, 1601 W. Taylor St., Chicago, Ill.

"feeling weak and dizzy." Almost daily her medication had to be withheld once or twice because of hypotension (90/54 to 72/50). When the dosage was reduced to 25 mgm. t.i.d. her normal pressure of 120/75 returned.

Case No. 4: This was a 31-year-old normotensive woman who became persistently hypotensive (90/60) on thioridazine 50 mgm. t.i.d. This was also noted when she received prochlorperazine 25 mgm. b.i.d. (86/60). She had no subjective complaints referable to her decrease in pressure.

Case No. 5: A 44-year-old woman showed no indication of side effects during her first month on thioridazine in doses to 150 mgm. t.i.d. Then hypotension as low as 80/60 was noted daily even as the dosage was being de-

creased. When medication was stopped a normal pressure of 118/75 returned.

COMMENT

It would seem that hypotension is at least one side effect that thioridazine (Mellaril) has in common with the other phenothiazines. The effect on blood pressure in these cases was unpredictable, not dependent on dosage or length of administration.

CASE REPORTS

CASE REPORT OF AN ACUTE OVERDOSAGE OF NARDIL¹

SAM H. BENBOW, M.D.,² AND WM. C. SUPER, M.D.³

The monoamine oxidase inhibiting drugs are becoming increasingly widespread in their usage. They are used extensively in depressions, and recently one of them, Nardil, has been suggested to be of value in the treatment of angina pectoris, rheumatoid arthritis, and psoriasis(1). Due to their widening employment and because they are used primarily in patients with depressive features we feel that acute toxic overdoses of the compounds of this group will appear in increasing frequency.

This case report concerns a 42-year-old white female, who has been a patient here 8 times since 1953, having been diagnosed as a schizophrenic reaction on 7 of the 8 admissions with paranoid type predominating.

The general clinical picture on previous admissions has been one of depression, psychomotor retardation, and paranoid delusions with occasional auditory hallucinations. Agitation has never been prominent.

Three days prior to the present admission a local physician had prescribed Nardil: tabs 60, 15 mgm. t.i.d. On that day the patient took 3 tablets and the following day, 4 tablets. On the day prior to admission she ingested 40 tablets at approximately 5:00 P.M. No nausea and vomiting or gastric lavage was reported. No unusual behavior was noted that evening. The patient was awakened at 6:00 A.M. on the day of admission after an uneventful night, and was noted by the husband to appear "drunk." She could not stand up, and slowly during the morning her speech became thickened and incoherent.

The patient was first seen on the psychiatric ward approximately 19 hours following the reported ingestion. When seen initially, she was unable to hold her head up, could

walk only with assistance, and was disoriented in all spheres. She rapidly became delirious on the ward, screaming incoherently, and required physical restraints.

Physical examination revealed her to be in good physical condition with the following additional findings: B.P. 170/120 (on all previous admissions B.P. approx. 110/70), pulse 100, respiration 22.

Fixed, equally dilated pupils and generalized hyperactive deep tendon reflexes were noted. There were no abnormal reflexes elicited, and eye grounds were not remarkable. Also prominent were isolated muscle fasciculations over trunk, extremities, and especially the jaw. There was no vomiting.

Her hospital course was complicated by a moderate dehydration on 2nd hospital day secondary to actively struggling against restraints in an extremely warm environment. Patient was rehydrated via nasogastric tube over next 24 hours. Patient's temperature rose to 105 degrees on 2nd day and remained for 24 hours at this level. Urine output during this time was 725 cc. No clinical evidence of infection was found; however the temperature dropped precipitously 12 hours after antibiotics were begun. A possible central hyperthermic reaction to the drug cannot be ruled out as the basis for the fever.

Over the next 5 days the above signs slowly disappeared. The muscle fasciculations were gone by the 3rd day, temperature normal by 3rd day, pupils returned to normal by 4th day, as did DTR's. Manic behavior, including disorientation, paranoid delusions, auditory and visual hallucinations, disappeared by 5th hospital day. B.P. slowly decreased to normal (110/70) by 5th day (all supine recordings). An FBS, Thymol Turbidity, and Ceph. Flocc. determined on 2nd hospital day and 3 wks. later were within normal limits.

It has been reported that side effects of continued Nardil therapy include: hypo-

¹ Phenelzine dihydrogen sulfate.

² Dept. of Psychiatry, L. S. U., New Orleans, La.

³ Director of Psychiatry, Independent Psychiatric Unit Charity Hospital, New Orleans, La.

tension, altered liver function tests, micturition, occasional rash, and nausea and vomiting(2). None was seen in this case of acute toxic overdosage. Hypertensive reactions and hypomania have been ascribed to sensitivity reactions(3). Features of severe overdosage reported and not seen in this case include angina-like pain, migraine-like headache, convulsive seizures, opisthotonos, and pinpoint pupils(4).

In summary the patient represented a medical supportive problem the main features being: confined to bed, sedated with Sparine, and strict attention to water and electrolyte balance. This oral dosage of

Nardil represents approximately 12 mgm./Kgm., and apparently was cleared by the patient in 5 days with no residual damage being detected. It is felt that high acute dosage of this drug represents a life-endangering situation if adequate supportive measures are not rendered.

POST-THYROIDECTOMY PSYCHOSIS TREATED WITH IMIPRAMINE

CHARLES A. CAHILL, M.D.¹

Psychosis associated with hypothyroidism is a well-known but complex disorder whose treatment is frequently unsatisfactory unless the symptomatology is a direct consequence of the deficiency in circulating hormone. If the latter be the case, thyroxin is curative; otherwise, treatment methods run the gamut with varying degrees of success. The following case report describes the use of imipramine² in a post-thyroidectomy psychosis which failed to respond to thyroxin alone.

Case Report: A 21-year-old WSM enlisted man came to the surgical outpatient department two months after a subtotal thyroidectomy for toxic goiter with complaints of weakness, tension, and feelings of worthlessness. When a repeat radioactive iodine uptake was found to be 8% (hypothyroid) and the conversion ratio, 15% (low euthyroid), thyroid extract in doses of one grain b.i.d. was prescribed. A few days later, however, the onset of overt somatic and self debasing delusions, blunted affect and perception, and psychomotor retardation made it

necessary to admit the patient to the psychiatric service. Significant details in his past history included a record of ineffective performance during basic training, difficulty in school, and a rigid, punitive upbringing in a small midwestern town. An EEG recorded not long after admission was characterized by diffuse slow activity of 4-5/sec. frequency, but it could not be stated with certainty that this pattern was of cortical origin; the entire record was felt to be of only borderline abnormality.

With a working diagnosis of psychotic depressive reaction secondary to thyroid deficiency, the patient was maintained on thyroxin alone plus the usual ward milieu therapy. His grossly psychotic symptoms gradually remitted to some extent over the next 6 weeks, but after he was transferred to an open ward, marked motor and intellectual retardation reappeared along with delusional ideas concerning what he fantasied to be the relationship between his operation and punishment for sexual activity (especially masturbation). A battery of psychological tests given at this time was suggestive of schizophrenia, but the results were not felt to be definitive in view of his overall depressed condition. The patient was not clinically myxedematous, although a repeat RAI was 3% and the conversion ratio, 7% (of questionable significance, however, in the presence of thyroxin therapy). Phenelzine³

¹ From the neuropsychiatric service, U. S. Naval Hospital, St. Albans, L. I., N. Y. Present address: Psychiatric Division, Bellevue Hospital, New York, N. Y. Opinions expressed herein are those of the author and do not necessarily reflect the views of the Navy Department or the Naval Service at large.

³ Supplied as Nardil through the courtesy of Warner-Chilcott Laboratories.

in doses of 15 mgs. t.i.d. was then added to the therapeutic regimen. The patient's condition nevertheless continued to deteriorate rapidly over the next 6 days, and because of the exigencies of his clinical status an alternative energizer, imipramine, was substituted for the phenelzine in 25 and then 50 mg. q.i.d. doses. The response to the latter was dramatic. Within two days his downhill course had been arrested (rapid action for imipramine, but by no means infrequently observed), and within 2 weeks his psychotic symptoms had disappeared entirely. The patient continued to receive imipramine for 5 additional weeks beyond the time he had reached what seemed to be his premorbid status. He was maintained subsequently on thyroxin alone and 2 weeks later was released from the hospital fully recovered. A 6 month follow-up report found the patient working steadily in civilian employment following honorable discharge from the service and getting along well on a maintenance dose of thyroxin.

DISCUSSION

The failure of this disorder to respond to thyroxin alone places it among the group of post-thyroidectomy psychoses that are un-

masked or precipitated by the surgery but are not caused strictly by the hypothyroidism. The patient's psychodynamics, as suggested by the delusional content and past history, and his relatively unremarkable physical status also imply reactive rather than endogenous etiologic factors, yet psychic energizers were employed nonetheless because it would be hard to discount endogenous factors altogether in the presence of demonstrated endocrinopathy. It is regrettable that clinical necessity dictated a switch in drugs 6 days after the commencement of therapy and confused the issue unavoidably in view of the well known time lag between the onset of medication and the remission of symptoms, but the almost immediate reversal of a progressively deteriorating course by a drug whose mode of action differs substantially from that of its predecessor presents a strong argument for the efficacy of the imipramine, rather than of the phenelzine. It would nonetheless be informative to try the latter again under suitable circumstances.⁴

"PLACEBO" (SIMULATION) ELECTROCONVULSIVE THERAPY

J. A. GUIDO, M.D., AND J. JONES, M.D.¹

The neurotic patient is seldom admitted to a state hospital facility unless, as in this case, the patient has no exact knowledge of his identity or place of residence. This report tends to emphasize the role of psychological factors which apparently were dominant in the therapeutic remission of psychogenic amnesia of events antedating admission to the hospital.

Present Illness: A 24-year-old, Caucasian, single, ectomorphic male was admitted with a history of retrograde amnesia, persistent and generalized cephalalgia, oscillopsia, and lethargy. A hyperthermia of 99° F. and EEG findings of "borderline diffuse slowing" suggested the presence of encephalitis; however, this was ruled out with a normal lumbar puncture and physical and neurological examinations. Hemo-

gram, urinalysis, and PBI were all within the normal range. The MMPI, multiple drawings tests, sentence completion tests, Bender-Gestalt tests, Wechsler memory scale, and Rorschach tests concluded "the hysterical components which are usually found with individuals with a neurotic type of dissociative reaction seem to be absent in this individual."

Hospital Course: The patient was placed on a "secure ward" with an active treatment program and ECT, which he frequently requested. However, periodic psychotherapy associated with 8 amytal-methedrine interviews were undertaken over a period of 6 weeks without improvement. He voluntarily participated in the various ancillary therapy programs and at no time displayed psychotic ideation nor affective disturbances.

Since he had indicated a desire to receive ECT, it was felt that the presence of auto-suggestion as well as the influences of mass suggestion by other patients could be utilized therapeutically (1). He was "prepared" and in-

¹ Respectively, Senior Psychiatrist and Resident Psychiatrist, Metropolitan State Hospital, Norwalk, Calif.

cluded with other patients awaiting ECT, thrice weekly. The treatments were undertaken in a room where another patient would receive ECT subsequently. An intravenous injection of 20 mgm. of Anectine was administered, a bite was inserted, and after the disappearance of the "muscular fibrillations," a very slight current (15 volts, 5 milliamps) was applied bitemporally over a period of one second; a few seconds later, the electrodes were removed and positive-pressure oxygen was administered until respirations returned. He remained apparently quiet but not unconscious. Several minutes after the second patient received a treatment, he displayed thrashing, purposeless movements and, later, complained of cephalalgia, myalgia, "confusion," and of a "wobbly" gait.

He asked when his memory would return, and was definitely assured that it would return after his sixth treatment. With each "placebo ECT" he became progressively "confused" and "amnesic" for recent events. After the sixth treatment, he jubilantly proclaimed complete restoration of his memory. Following his ninth "placebo ECT," he refused to remain in the hospital for further psychiatric care; occasional telephone calls from the patient report he is gainfully employed.

SUMMARY AND CONCLUSIONS

Nine placebo electroconvulsive treatments produced a definitive symptomatic

remission of psychogenic amnesia in a patient diagnosed as Dissociative Reaction.

The patient's closeness with the doctor, ward personnel, and ancillary therapies intensified the element of suggestibility and the "placebo effect" (2) of electroconvulsive treatment. This was apparent despite the exclusion of "hysterical components" by psychometric examinations.

At no time was the patient fearful or undesiring; as a matter of fact, he was overly willing and frequently requested electroconvulsive treatments. Unlike the use of simulation ECT in chronic schizophrenic patients, this report dismisses the utilization of fear and the loss of consciousness as important therapeutic factors (3, 4). This article also demonstrates the need for more extensive studies to encourage recognition of underlying "neurotic and hysterical factors" when describing the therapeutics of electroconvulsive treatments.

CAMPTOCORMIA—A RARE CASE IN THE FEMALE

FREDERIC PAUL KOSBAB, M.D.¹

Camptocormia, or the hysterical bent back, has so far not been reported in women. The syndrome was mentioned first in the literature by Brodie (1) in 1837 and later by several others during and after both World Wars when young soldiers employed this hysterical phenomenon to escape from hardships of military life and combat situations (2-6). In the French literature, cases of camptocormia in non-military personnel from industrial areas have been reported (7), but none in a female.

It therefore appears warranted to report the following case of camptocormia in a female patient:

A 28-year-old housewife, mother of 4, twice divorced and living in separation from her 3rd husband, entered the hospital in a stooped body posture, her back bent sharply from the hips in an angle of about 70 degrees. She complained in an angry and belligerent tone of voice that this painful "back condition" had now been present for 6 months, and before that on and off for 10 years, the single "spells" lasting from 1 day to several months. She had had numerous medical examinations, including X-rays, but the doctors had "failed to find anything organically wrong with her back"; however, she felt completely incapacitated and unable to take care of household and children.

The patient presented her grotesque posture at all times when walking around or standing but was able to straighten her back completely

¹ 600 9th Ave., Seattle 4, Wash.

when placing herself in the recumbent position. This latter phenomenon, together with absence of any structural lesions, appeared diagnostic for camptocormia.

The patient, whose insistent and belligerent demands for further diagnostic measures and orthopedic procedures were ignored, was consistently and in a non-punitive manner told to "straighten up a bit every morning" (an approach which was already successfully employed by Hamlin (3)); she gave up her functional symptom completely after 2 weeks of hospitalization. Subsequent psychotherapy which was partly supportive, partly uncovering, revealed the patient to fall in the group of passive-aggressive personality trait disturbances of the aggressive type, which factor was mainly responsible for her difficulties and intense struggles in life, including 3 unsuccessful, combative marriages, a very hostile and ambivalent relationship with mother and sister, and an altogether very unsatisfactory domestic situation. Under the circumstances, it appeared obvious that the hysterical symptom of camptocormia had served as effective means to escape from the emotional consequences of a more and more unbearable life situation, with relief of anxiety representing the fundamental and primary gain.

Etiologically, no significant back injury was found or claimed. A car accident, some 10 years ago, was mentioned by the patient but not connected with the back syndrome. No other claims were ever made.

The outlook for this patient appeared guarded, although no relapse had occurred in the hospital, and after a total of 9 months of observation further follow-up was felt to be desirable.

The aforementioned case of camptocormia in a female is believed to be the first on record. The question why this functional syndrome, well known in males for over a century, has not been described in women before, appears of psychiatric interest and worth some further investigation.

ENURESIS AND THYROTOXICOSIS: A BRIEF CASE REPORT

NORMAN SHER, M.D.¹

Descriptions of the background and personality of the male enuretic (1) and thyrotoxic individual (2) have several features in common. The most notable of these are a hostile, rejecting mother figure in early life, subsequent identification with such a figure, and the persistence of passive, feminine personality traits. No reported cases were found in which these two disorders occurred together.

Case Report.—The patient is an 18-year-old white male first seen for nocturnal enuresis which started at age 15. Shortly before the

onset of the enuresis his family had moved and bought a motel because the father had crippled his left hand and lost his job. The patient had been seen and treated by a local physician, but continued with his difficulty. At age 18 he enlisted in the Army. His enuresis persisted and he was seen by the CU clinic during basic training. No organic disease was noted. At his permanent assignment he was again referred to a medical facility and thence to the psychiatric service. He was a retiring, passive individual who felt he and his mother were alike, and who seemed preoccupied with the idea of "having to help" his mother. It was thought that his enuresis was on a psychogenic basis. He was followed for several months with water restriction, probanthine and supportive psycho-

¹ Manhattan State Hosp., Ward's Island, New York 35, N. Y.

therapy. His enuresis, however, persisted. At no point was any evidence of hyperthyroidism noted. He then was convicted of theft, and placed in the stockade. Two weeks later he complained of increasing nervousness and fatigue, and was noted to have a diffusely enlarged, non-nodular thyroid, a fine tremor and a pulse rate of 120. An I 131 uptake was 72% in 24 hours, a PBI 27 mg.% and a BMR plus 41. A diagnosis of diffuse, toxic goiter was made, with the suggestion that this be treated surgically after medical preparation. He was hospitalized, and treated with propylthiouracil and later Tapazole. In two months his PBI had dropped to 9.5mg.% and his BMR to plus 5, but he was still judged to require further presurgical preparation. The patient continued with his enuresis while in the stockade and during the first week in the hospital, but after that had no difficulty.

DISCUSSION

There are a number of interesting features to this case, among which are the late onset of the enuresis and the acting out

(theft). Of major interest, however, is the relation of the enuresis to the thyrotoxicosis. Two possible explanations of this are :

1. The enuresis might be an early (and hitherto undescribed) sign of hyperthyroidism on physiologic grounds alone.

2. Both the enuresis and the thyrotoxicosis might represent different, inter-related psychophysiologic attempts in a given individual to cope with his life situation.

It seems unlikely that enuresis as a sign of early hyperthyroidism would not have been previously noted. This, along with the personality similarity in the (male) enuretic and thyrotoxic individual tend to support the latter hypothesis.

HISTORICAL NOTES

HENRY M. HURD AND THE JOHNS HOPKINS "BIG FOUR"

JEROME M. SCHNECK, M.D.¹

Henry M. Hurd was a man of great capability and with a distinguished career. Some of his accomplishments are remembered, but others were never widely known. Reluctantly, he prepared autobiographical information that appeared under the heading, "Some Random Recollections," as the last chapter in a biographical volume by his friend and admirer, the well known gynecologist Thomas S. Cullen(1). The book(2) with its personal reminiscences of Hurd has apparently received little attention. It is a small work, less than 150 pages, including a bibliography of Hurd contributed by Minnie Wright Blogg, Librarian at The Johns Hopkins Hospital. Cullen prepared his book at the request of members of the Hospital Board of Trustees. He had joined the hospital in 1891, encountered Hurd professionally, and became one of his friends. Later he wrote "... until now I have never had the slightest conception of the tremendous amount he has accomplished and of how largely he has been responsible for the phenomenal success of The Johns Hopkins Hospital"(2).

Hurd tells us he was born in Union City, Michigan, on May 3, 1843, the son of a physician, Dr. Theodore Canfield Hurd. His mother was Eleanor Eunice Hammond. His father is described as a man of energy, foresight, business acumen, and love for his profession. He was a graduate of Yale Medical School.

Henry Hurd's early years were spent on a farm near Union City. His father died in 1845. His mother married a younger brother of her deceased husband. This brother and another were also physicians. Still other relatives were of this profession. His stepfather was recalled as a kind man, interested

in the education and development of his three stepchildren.

In 1854 the family moved to Galesburg, Illinois. There, at age 14, Hurd entered Knox College. For reasons of health and because of conflicts between rival factions for control of the college, Hurd remained at home for one year after having completed two years of study at the college. He taught at a country school. In 1861 he entered the third year at the University of Michigan in Ann Arbor and was graduated in 1863. He appreciated the change in school because contacts with teachers and students coming from distant places were more stimulating. Among the most stimulating influences was Andrew D. White who subsequently became President of Cornell University.

Hurd studied medicine under a preceptor, took a course of medical lectures at Rush Medical College in Chicago and another at the University of Michigan. He was graduated in medicine in March, 1866. Failing to gain entrance into the United States Navy on the ground of being a poor health risk, he was to say later, "I now recognize that this unkind verdict was probably one of the best pieces of good fortune I ever had"(1).

C. B. Burr, Hurd's successor at a later position in Pontiac, Michigan, tells us that Hurd's preceptor in his medical studies was his stepfather, and that after his graduation as a physician he did hospital work in New York where he studied also before moving to Chicago(3). There he was in general practice for two years.

In 1870 he was invited to serve as a medical officer in the State Hospital for the Insane at Kalamazoo, Michigan. E. H. Van Deusen was in charge. "I expected to remain during the summer only, but became so much interested in the work that I accepted a permanent appointment and remained in Kalamazoo eight years"(1). In 1878 he became assistant superintendent but left after a few weeks to take charge of the Eastern

¹ Clinical Associate Professor of Psychiatry, State University of New York College of Medicine at New York City; Address: 26 West 9th Street, New York 11, N. Y.

Michigan Hospital for the Insane at Pontiac. "This institution I opened, organized and conducted for 11 years, or until 1889"(1). Hurd became active in the Association of Medical Superintendents of American Institutions for the Insane (later the American Medico-Psychological Association and finally the American Psychiatric Association) (4). He served as Secretary (1893-1897) and President (1898-1899). He edited the *American Journal of Psychiatry* from 1897-1904. In his hospital work he opposed unnecessary restraint of patients, favored their employment, supported the cottage plan and was associated with all progressive developments. He was active in several medical organizations.

In 1889 he was appointed superintendent of The Johns Hopkins Hospital, which office he held until 1911, when he retired to become Secretary of the Board of Trustees. Burr tells us that Hurd hesitated to accept the Johns Hopkins appointment. It meant relinquishing his clinical psychiatric connections. He was strongly encouraged to accept(3). He had already started a new institution and now he had a similar opportunity. Cullen wrote, "In this institution he was destined to establish later the most harmonious relationship between the hospital and The Johns Hopkins Medical School which opened its doors in 1893. His wise council, his broad vista and his tact have in large measure been responsible for the continuous cordial and intimate relations that have always existed between the medical school and the hospital"(2). It has been stated that Hurd's abilities and his character are reflected especially well in the series of annual reports of the Hospital from 1889 to 1911. In his first report he mentioned the appointments of Osler, Welch, Kelly and Halsted. He stressed the services of Billings (a later professional collaborator(15)), and President Gilman especially.

Hurd initiated *The Johns Hopkins Hospital Bulletin* and *The Johns Hopkins Hospital Reports*. He served as editor of both and many an article had to be reworked completely by him. He has been accorded much credit for their early success. His own writing continued with emphasis on medical education, nursing education, hospital management and psychiatry. One of Hurd's

best known publications is his edited four volume *Institutional Care Of The Insane In The United States And Canada*(5). He alone wrote the first volume.

For a view of the man and his impression on others we turn to Cullen's colorful description :

Dr. Hurd did not hold himself aloof from the house staff, but after the evening meal often dropped into the reading room to have a chat with the men congregated there. Every now and then an informal invitation came to dine with Dr. Hurd, Mrs. Hurd and his daughters. These were red letter occasions—events never to be forgotten.

Every one of the men who was connected with the hospital during Dr. Hurd's time has a vivid recollection of that tall, slender figure passing silently down the corridors with his head bent slightly forward and apparently walking on air, his tread was so light. He rarely was content to mount the stairs one step at a time, he invariably went up two at a time with his arms outstretched as if he contemplated an aerial flight.

Celebrated men who are closely associated with large numbers of young men are often given a special name as a mark of the esteem and affection in which they are held. When the men of the hospital staff of 20 years ago gather together and discuss old times they always refer to "Uncle Hank" with the warmest regard.

The visitor to the hospital—the one who comes to stay a few weeks or months—while impressed by the good work done in the various departments and by the original articles published by the hospital is more impressed by the spirit of cooperation and good fellowship that exists in the hospital and medical school. Dr. Hurd and the "Big Four"—Drs. Osler, Halsted, Kelly and Welch—have in large measure been responsible for this delightful atmosphere.

Many of the senior members of the hospital staff have been geniuses and it is a well-known fact that geniuses frequently become so engrossed in their individual subject that they are temporarily totally oblivious to the fact that other people have to be considered and that these people have precisely the same rights and privileges as they. A tactful, gentle, but firm tug emanating from the superintendent's office would awaken such an individual from his reverie. It was this absolute fairness on the part of Dr. Hurd that won for him the confidence and affection of the senior staff. They

knew that they would always get a square deal(2).

Hurd had been carrying the entire responsibility for editing the hospital publications. On Jan. 9, 1899 Osler wrote to him suggesting that "there should be an Editorial Committee composed of you and Mall, and Abel, and Howell and a couple of the younger men, with Smith as Secretary to do the proof-reading and to relieve you of all the worry of it"(6).

Dr. Hurd's increasingly burdensome activities, however, probably did not account for the impression of a "crotchety exterior" that some persons observed. They never detracted from his helpfulness. Heuer recalled, "He did many kind deeds for young men about the hospital, few of which even became known. A rather forbidding man because of his caustic tongue, he had a keen sense of humor"(7). Hugh Young told of Hurd receiving letters from prominent physicians for aid in retrieving manuscripts that Welch permitted to accumulate without reply(8). In addition to other tasks, Hurd would hunt through Welch's collections, during his absence, to find and return the missing items. Amongst these observations are others which pictured him as often cautious and non-committal in letters and transactions(9).

It was probably no accident that Cushing, telling of the youth of Osler, Welch, Halsted and Kelly at the time of their Hopkins appointments included Hurd too(6). And Welch's biographer, describing the "Big Four," added,

President Gilman himself undertook to find the last of the men absolutely necessary for the functioning of a hospital, the superintendent, and chose the head of an insane asylum in Pontiac, Michigan, Henry Hurd . . . Hurd at Johns Hopkins proved to be the ablest hospital superintendent of his time in America (10).

Hurd was linked directly with the Big Four also by Lewellys Barker(11). Yet there were other men of great merit in the early years of the hospital and medical school. Mall is one example(12). Hurd alone seems consistently to be accorded this fifth position. It is of interest too that Hurd shared

the historical perspectives of his colleagues and was especially concerned with early data about The Johns Hopkins Hospital (13).

To raise the question whether the "Big Four" reference should be more suitably the "Big Five" may appear to be stretching a point. The fact is that Kelly, according to his recent biographer, "always insisted that Hurd was as much one of the founders of the School of Medicine as were the original four department heads"(14). This precise statement is amply supported by an assertion of Cullen :

I have always felt that Hurd should have been included in Sargent's portrait group of the "Big Four." It should have been five. In his life Dr. Hurd did as much for Johns Hopkins as any of the four and it might easily be shown that he did as much for them as he did for Hopkins.

Welch and Osler and Halsted and Kelly would never have had the reputations they made, except for Hurd. He founded the Hopkins Hospital Bulletin before there was a medical school and he started the Hopkins Reports and edited both for years. The four others recognized in theory that they should record what they were doing and finding out ; but it was Hurd who made them do it. He kept after them all the time to write up their experimental work and their interesting cases, their clinical observations and laboratory findings, for the Bulletin first and then for the Reports ; never let them rest until they had done it.

And that more than anything else, as they all recognized was what made Hopkins' name, and theirs. Especially in Europe. Hopkins Bulletins were known in the European clinics before the hospital had been going three years. So, thanks to Hurd, were the names of the "Big Four." Like most men who do things, they got their satisfaction in doing them. It was Hurd who made them write and made them famous (16).

Some aspects of Hurd's work and personality have been mentioned briefly, and the idea of a "Big Five" has been suggested by documentation and implication. But there is more to the essence and importance of his contributions. His activities, writings, personal associations and the full impact of his efforts must await another report.

THE FIRST ELECTROCONVULSIVE TREATMENT GIVEN IN THE UNITED STATES

SYDNEY E. PULVER, M.D.¹

The readmission of the first person treated with electroconvulsive therapy at the Institute of the Pennsylvania Hospital provided the stimulus for this brief note on the introduction of electroconvulsive therapy to the United States.

As far as I can determine, the first treatment in the United States was given by Dr. Victor A. Gonda. It is best described in the words of his son :

In midsummer of 1939, dad was in communication with Cerletti and in November of that year he received delivery of an Italian machine (including a separate ohm-meter) made by G. Zurli and Dr. A. DeRegibus in Genoa, Italy. For the first two months dad did not begin treatments, while in his cautious and methodical manner he tested out the apparatus on experimental animals (producing convulsions). I recall vividly also, just before Christmas of 1939, his placing the electrodes on his own thigh, experiencing a violent contraction of his muscles and injuring his leg which hit the table. Subsequently, he was concerned about the possible pain patients might experience were they not immediately rendered unconscious. This delayed his giving of the first

treatment until late January of 1940 at the Parkway Sanitarium in Chicago. I recall the anxieties and the tensions experienced with the giving of the first few treatments, having accompanied my father to the Sanitarium on those occasions. By May of 1940, dad had treated several patients and had learned many nuances relative to the treatment.

The first treatment mentioned above was given some time before January 20, 1940. Shortly thereafter, on February 6, 1940, Doctors David J. Impastato and Renato J. Almansi treated their first patient at Columbus Hospital, New York City, using a machine brought by Almansi from Italy.

Meanwhile, interest was aroused, and American machines were being constructed. Using a machine constructed by Mr. Franklin Offner of Chicago, Dr. Douglas Goldman treated his first patient on April 23, 1940 at Longview State Hospital, Ohio. An earlier American machine, designed by Dr. Joseph Hughes, was constructed by Mr. Fritz Schindler at the Institute of the Pennsylvania Hospital. Construction was finished late in 1939, and a series of cats and monkeys were treated and later studied for cerebral damage. The first human treatment with this machine was administered by Dr.

¹ Institute of the Pennsylvania Hospital, Philadelphia, Pa.

Hughes and Dr. Lauren H. Smith on May 1, 1940. The subsequent history of this patient is interesting. At the time of her first treatment she was 50 years old and had been hospitalized for 4 years with "intractable" involuntional depression. Twelve Metrazol convulsions had previously been ineffective. Treatment on May 1 was subconvulsive; and it was not until the fifth treatment on May 17 that a convulsion was

produced. After 23 treatments in the next several months, she showed no signs of depression, and was discharged in 1941. She remained well for 18 years! In 1957 she was hospitalized with a second depression, which required 9 treatments to effect a remission. Although the original machine still resides at the Institute, sentiment did not prevail and she was treated with a more modern apparatus.

COMMENTS

A NATIONAL INSTITUTE OF SOCIAL AND BEHAVIORAL PATHOLOGY

Our discussion of research areas in the common frontiers of psychiatry and law(1, 2) far from exhaustive though it is, has nevertheless indicated how vast the field of psychiatry and the law is now perceived to be. The map of common problems of social and behavioral pathology has unfolded gradually through the years. In our view the moment is opportune to provide a national center of investigation designed to provide a continuing stream of initiative, an integrating focus, and a place of work entirely devoted to the study of social and behavioral pathology.

Such an institute should be geographically inclusive in the sense that it should take intellectual responsibility for examining the problems in the national context. It will naturally assume some special responsibility for the locality where it may be situated. Preoccupation with national trends and potential developments would not blind the Institute's investigators to the world context, and to the importance of comparative research studies which seek the significant phenomena regardless of political boundaries. A National Institute of Social and Behavioral Pathology would be a natural participant in the work of similar establishments at every level—personal, local, national, international.

A broad responsibility of the Institute would be to aid in the clarification of national achievement objectives in the fields of law and mental health. It would undoubtedly operate within the fundamental assumptions of human dignity which are incorporated in the aspirations of American society and partially articulated in such instruments as the Universal Declaration of Human Rights. Goal clarification calls for the presentation of long-range, middle-range, and more immediate objectives.

The clarification of goal called for above must be conducted in the light of dependable information about the remote and recent past, and the projection of the

future. Since existing machinery for the obtaining of essential statistics is wholly inadequate, one prime task of the Institute would be to set up procedures for the collection, evaluation and publication of needed information concerning the incidence and prevalence of various forms of crime and alleged crime, their disposition by the social, police, prosecutory, judging and incarcerating agencies, including probation and parole. Hopefully these initiatives would lead to the development and dissemination of more psychologically illuminating data.

The core of the Institute's work, as indicated throughout our papers, is the discovery and verification of social and behavioral hypotheses that explain the individual and social dislocations that concern us. Thinking nationally, it is evident that the varied circumstances among the several States permit us to design experiments in nature—using States as "control" for each other, comparing by field studies factors—demographic, economic, ethnic, for instance—that predispose to high rates of crime in some areas and to greater conformity in others. Investigative methods would be in no wise restricted to this pattern, of course. As our review of promising lines of attack has suggested, there is room for much versatility which it will be one of the principal aims of the Institute to encourage. It is of fundamental importance to provide a hospitable environment for the pursuit of every promising lead, and to guard against the domination of inquiry by advocates of any one set of factors, whether economic, political or professional.

Besides the broad definition of the over-riding objectives of American society the problem will be to study a limited array of socio-legal possibilities in terms that bring out the social costs as well as the probable gains of following a particular sequence of change. In terms of culture, social class,

interest group, and personality form these costs (and gains) need to be brought into the clear light of rational assessment.

In a word we are affirming that the many common frontiers of psychiatry and law involving social and behavioral pathology now justify a national effort at joint exploration, settlement, and incorporation into the

fraternity of organized intellectual states.
Lawrence Zelic Freedman, M.D.
Harold D. Lasswell, Ph.D.

CORRESPONDENCE

SENSORY DEPRIVATION

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : Referring to the letter of Jack Arbit, PH.D., in the November 1960 issue which gives important information about early research on the subject of sensory deprivation, quoting other research in the same area recently published in the APA Journal, may I point out that some of the work which was done during the war in Switzerland has not been quoted by any author in your journal.

Your readers may be interested to know the results of the research which I published in *Schweizerische Zeitschrift für Psychologie*, 1948 Band VII. Heft 1, Verlag

Hans Huber, Bern, entitled *Die Psychologie der isolierten Gruppe*. The observations were made in Swiss labor camps during World War II for refugees and aliens who lost their passports because their countries of origin were invaded, and also in remote Swiss mountain areas and state hospitals.

It is to my knowledge the only psychological treatise commended by Dr. Albert Einstein, who in a letter to me made an interesting comparison between the psychological phenomena I observed and certain electrical physical phenomena.

Ben A. Finkelstein, M.D.
Eastern State Hospital,
Lexington, Ky.

TREATMENT IN TRANSVESTISM

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : In the September, 1960 issue of your *Journal*, Dr. Veronica M. Pennington in the paper "Treatment in Transvestism" describes a successful outcome in the treatment of a 31-year-old transvestite. It is concluded : "Transvestism is perverted behavior which has been corrected chemically by the phrenotropic agents nialamide, chlorpromazine, and meprobamate. . . ."

This case report calls to mind a 40-year-old divorced man who consulted me as an outpatient in July 1956 with a chief com-

plaint of transvestism since age 12. He was seen in 4 sessions of psychotherapy. During the last session he announced his intention to marry again the following September.

He consulted me again in July 1960 because of trouble in being assertive in his marriage, both with his wife and teen-age stepson. Transvestism was not a symptom nor had it been in the intervening years.

The effective agents in psychiatric interventions are difficult to specify.

Robert D. Gillman, M. D.,
Washington, D. C.

ORDINAL POSITION

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : Dr. Hanus J. Grosz' comment on the supposed lack of significance of ordinal position in the family (*Am. J. Psychiat.*, 117 : 165, 1960) omits consideration of one of the most important papers on the subject, McArthur's "Personalities of First and Sec-

ond Children (*Psychiatry*, 19 : 47, 1956). This paper seems to have appeared too late to be included in the 1956 reviews by Koch which Dr. Grosz quoted.

The McArthur paper, based on a three generation study of normals, suggests that "the first child in a family is more commonly adult-oriented, while the second child is

more likely to be peer-oriented." It also indicates that "of the various traits that arise from first-born and second-born orientations, sensitive seriousness in the first and easy-going friendliness in the second seem best documented."

The McArthur study appears to be both thorough and accurate, and apparently in accord with much clinical experience. The reason for McArthur's findings might be found by viewing the family as a hierarchical structure (N. S. Lehrman: "The

Family: a Biosocial Hierarchy; How Democracy Begins at Home," paper read before the A.A.A.S., Dec. 1959). In this hierarchy, particular importance for any one individual can be seen as resting on the person next above him. The mother will usually be next above the adult-oriented oldest child, while an older sibling will tend to be next above the peer-oriented younger sibling.

Nathaniel S. Lehrman, M.D.,
Great Neck, N. Y.

REPLY TO FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: A review of the literature on the significance of ordinal position in the family does not support the claim that this factor can be singled out as a determinant of specific personality traits. In individual instances in which ordinal position appears to be of importance its meaning differs greatly from one person to another and from one intrafamilial setting to another.

In regard to the McArthur study, quite apart from its own merits, one cannot help but question the pertinence of his conclusions to the significance of ordinal position in general. The participants in his study were drawn from a group of volunteers at Harvard University and as McArthur himself remarks, "It is possible, of course, that the phenomena reported are peculiar to the

Harvard Scene." This impression is further reinforced by McArthur's observation that even within this highly selected population sample "among the private-school boys . . . 44% of the first-born were classified in complete agreement with first child theory, while only 25% of the public-school first borns were so typical."

There are other equally obvious biases which have gone into the McArthur study which cannot be discussed in this brief answer to Doctor Lehrman's letter. At any rate, it hardly seems warranted to alter one's conclusions which are drawn from the literature as a whole, on the basis of this study.

Hanus J. Grosz, M.D.,
Albert Einstein College of Medicine,
Yeshiva University.

IN MEMORIAM

ROBERT BUSH MCGRAW

1896-1960

Robert Bush McGraw, Professor of Clinical Psychiatry of the College of Physicians and Surgeons of Columbia University, died at the Harkness Pavilion of the Presbyterian Hospital in New York City on October 2, 1960, at the age of 64.

He was born in Cortland, N. Y., on November 16, 1896. He came from a family of whom many were good doctors, including his maternal grandfather who served his community for a half century. Dr. McGraw's early education was in McGraw, a small village near Cortland. When he was 14 his family moved to England and there he attended the Boys' Grammar School at Hitchin, Hertfordshire, later completing his secondary education at the Finsbury Technical College in London, England. In 1914 at the age of 18, he entered Cornell University for his undergraduate years and continued in the same school for his medical training, receiving his Bachelor's degree in 1918 and his M.D. in 1921. During his school years he had many interesting positions in hospitals and spent one summer in the office of his uncle who was a medical practitioner.

After graduating from medical school and before entering upon his internship on the Second Medical Service at Bellevue Hospital, he spent a 6 months' period as medical intern at the New York Hospital, Westchester Division, at that time Bloomingdale Hospital, and was assistant physician there from January 16, 1924 to June 3, 1925.

Dr. McGraw became Instructor in Psychiatry at the College of Physicians and Surgeons, and Clinical Assistant at Vanderbilt Clinic in 1924, and between 1925 and 1927 was closely associated with Thomas W. Salmon, the Professor of Psychiatry at Columbia. About the same time he joined George Draper's Constitutional Clinic and collaborated with him in the formulation of one of Dr. Draper's 4 panels, the psychiatric

panel, and in the investigation of peptic ulcer and other psychosomatic problems. Dr. McGraw's rise in the Department of Psychiatry was rapid. He assisted Dr. Salmon in plans for The Medical Center then moving to Washington Heights and was made Chief of the new Outpatient Department and Clinical Professor of Psychiatry in 1928.

One of Dr. McGraw's chief duties as head of the Psychiatric Outpatient Department was the organization of the teaching of the third year clinical clerks. He also established a Children's Psychiatry Department as part of the service. Dr. McGraw gave a great deal of time and enthusiasm to his teaching and was one of the first to advocate visits by clinical clerks in psychiatry to the homes of their patients, a practice later incorporated into comprehensive care at other medical centers. He organized the first psychiatric consultation service for the Presbyterian Hospital and at his death was Attending Psychiatrist there. In World War I as a student at Cornell, Dr. McGraw was a member of the Student Army Training Corps.

During World War II he was a Senior Consultant for the Veterans' Administration and did much to arrange for the screening and treatment of veterans needing psychotherapy. He also helped to organize a psychiatric clinic for the Home Service Department of the American Red Cross.

In 1944 and 1945 Dr. McGraw administered a training program for Army doctors at the Vanderbilt Clinic. This consisted of three twelve-week periods of training and clinical instruction in the Fundamentals of Neuropsychiatry for a total of 150 officers.

In addition to teaching and lecturing at Columbia he came to grips with many practical problems of his day. Before the formation of the American Board of Psychiatry and Neurology he published a paper in the *Journal of Nervous and Mental Disease*,

February 1931, "Are Neurology and Psychiatry Separate Medical Entities?" He said, "I think we must recognize the fact that the public is choosing psychiatrists under that label more and more; and, further, that they are beginning to understand that a psychiatrist means a physician, medically trained, and not simply psychologically and pedagogically trained. A neurologist should be extremely well trained in neuroanatomy and perhaps the notion should be expressed that a man might be both neurologist and psychiatrist but could be either." He was interested in problems of hypochondriasis, insomnia, and recoverable mental disturbance of the aged. He also addressed himself to the serious problems of medical and psychiatric indications for abortion and alerted all of us to the importance of knowing the law of the land and time. He made very worthwhile contributions to the *American Handbook of Psychiatry*. In his teaching and practice he was interested in all forms of treatment which brought the psychiatrist's skills to the greatest number of patients.

Dr. McGraw was chairman or president of most of the important New York psychiatric societies. His philosophical, historical and literary contributions at the Vidonian Club, which he loved, will be long remembered. To all associated with him in

school, hospital and the community he was the ideal of a good doctor, friend and humanitarian.

As a member of the Madison Avenue Presbyterian Church, he took interest in adding to the membership's information regarding medical and psychiatric subjects and assisted in setting up standards for selection of missionary personnel for the Presbyterian Church. In recognition of this service he received a citation on the 29th Anniversary of the Missionary Society's Medical Department. He was active in the State Mental Hygiene Commission of the State Charities Aid Association, a member of the Council on Widows and Orphans and a member of a committee to study the care and education of epileptic children in public schools and homes under the Board of Education of the City of New York. Dr. McGraw was also a member of the Advisory Qualifying Committee of the Workmen's Compensation Board of the New York Academy of Medicine and member of its Committee on Medical Information.

Dr. McGraw married Catherine Ruth Ross on January 2, 1924. Besides his wife, he is survived by a daughter, Anne Barbara McGraw, and a son, Robert Bush McGraw, and 3 grandchildren.

James H. Wall, M.D.

NEWS AND NOTES

DR. DAVID RAPAPORT.—At the early age of 49 occurred the death, December 14, 1960, of Dr. Rapaport, psychologist of the Austin Riggs Foundation at Stockbridge, Mass.

Dr. Rapaport was born in Hungary and received the degree of Ph.D. in psychology from the University of Budapest.

Coming to the United States in 1938, he joined the staff of the Osawatomie (Kansas) State Hospital, going later to the Menninger Clinic at Topeka as chief psychologist, where he became the director of research.

Since 1948 he had been a member of the Austin Riggs Foundation as research associate in charge of psychology and director of psychological testing methods, as described in his *Manual of Diagnostic Psychological Testing*.

Rapaport's most ambitious publication is his *Organization and Pathology of Thought*, published in 1951 by the Columbia University Press. This huge volume represents an enormous amount of work, including the selection and translation of 27 major contributions in the German and French literature, many not readily accessible to English readers, and supplying as well extensive running commentaries throughout. In an ample concluding chapter Rapaport seeks to integrate the texts of the various authors and adds relevant more recent data. The keynote he followed in this work was the statement in the first line of his Preface: "The knowledge that thinking has conquered for humanity is vast, yet our knowledge of thinking is scant."

AMERICAN PSYCHOSOMATIC SOCIETY.—The Society's 18th annual meeting will be held at Chalfonte-Haddon Hall, Atlantic City, April 28 to 30, 1961. The meeting will begin Friday evening, April 28, at 8:30 o'clock.

Registration is Friday afternoon from 3:00 to 5:00 and from 7:00 p.m. The registration fee for non-members of the Society is \$5.00. Students, interns, residents, and fellows, \$1.00 and presentation of proper identification.

THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY.—The Board will hold 3 examinations in 1961: March 20 and 21—New Orleans, La.; October 9 and 10—Chicago, Ill.; and December 11 and 12—New York, N. Y.

Effective January 1, 1962, the following fee schedule will be adopted: application fee, \$75.00; examination fee, \$100.00; re-examination fee (complete re-examination), \$100.00; re-examination fee (1 or 2 subjects), \$75.00.

DR. WALTER WOODWARD.—One of the leading exponents and practitioners of occupational psychiatry in the United States, Dr. Walter D. Woodward, consulting psychiatrist to the American Cyanamid Company, died Oct. 8, 1960, at the age of 44.

A graduate in Arts from the University of Michigan, Dr. Woodward received his M.D. degree from the University of Virginia in 1943. He took graduate work in psychiatry at the U.S.P.H.S. Hospital on Staten Island and at New York Hospital. He became a member of the medical staff of the American Cyanamid Co. in 1947 and continued in that position until his death.

As exemplar, planner and teacher of psychiatry in industry, particularly in its preventive aspects, Dr. Woodward had created for himself an enviable career. The value of his leadership was widely recognized.

SECOND INTERNATIONAL CONFERENCE OF HUMAN GENETICS.—This Conference will be held in Rome, Italy, September 7-12, 1961.

The 7th International Congress of Neurology will be held in Rome at the same time and a joint session between the two bodies will be arranged.

The Genetics Conference will be held in the Conference Building of the Food and Agriculture Organization of the United Nations. Professor Luigi Gedda is chairman of the organizing committee.

Registration fees: full membership, including proceedings, \$30.00; without proceedings, \$15.00; associate membership, \$10.00.

Following the Conference an official tour

will be arranged to Naples, Sorrento, Amalfi, Salerno and Paestum.

THE YALE CENTER OF ALCOHOL STUDIES AND LABORATORY OF APPLIED BIODYNAMICS.

—The Center regretfully announces the decision of the University that, valuable as the work of the department has been for the past 40 years and promises to be in the future, its continuation as a part of Yale University is inappropriate.

The major reasons for this decision are: the diversity of academic disciplines represented in the Center's research program, and the applied rather than purely academic nature of some of its responsibilities and activities, make it difficult to locate the organization in any of the traditional departments at Yale under its current educational policy; furthermore, the University cannot increase its contribution to the necessarily expanding financial needs of this program.

The Yale Corporation has pledged continued support to the Center for a reasonable period to allow, first, completion of current research programs and, second, development of steps to facilitate in a setting other than Yale the orderly continuation of its documentation, publication, educational and other activities.

The projected 19th annual session of the Summer School of Alcohol Studies, and the Alumni Institute already announced to its 3,300 graduates, both scheduled for July 1961, are to be held at Yale University as planned.

ARBEITEN AUS DER DEUTSCHEN FORSCHUNGSANSTALT FÜR PSYCHIATRIE IN MÜNCHEN.

—22nd ed. Max-Planck-Institut. (Berlin, Göttingen, Heidelberg: Springer-Verlag, 1960. No price quoted.)

This weighty volume is an assemblage of 53 papers by 28 authors emanating from the Max-Planck-Institut and representing recent work at this Center.

The whole range of neurological, psychological and psychiatric subjects is represented in this volume, in which the actual offprints have simply been bound together.

NURSES ATTEND APA INSTITUTE.—Psychiatric and mental health nursing consultants

met in Sale Lake City on October 16, 1960, the day before the Mental Hospitals Institute of the American Psychiatric Association, to discuss programs in their states and regions. Margaret L. Cavey, psychiatric nursing consultant, chaired the meeting. Among the topics discussed were: the changing role of nursing personnel in the open hospital; psychiatric units in general hospitals; care of the aged in nursing homes and the role of the LPN in psychiatric hospitals.

5TH CONGRESS OF LEGAL MEDICINE AND OF SOCIAL MEDICINE.—This Congress will be held in Vienna, May 22-27, 1961. Professor Dr. Leopold Breiteneker, Director of the Institute of Legal Medicine, University of Vienna, is President. All aspects of forensic medicine will be represented.

Further information is available from the Secretariat of the 5th Congress of the International Academy of Legal Medicine and of Social Medicine, Vienna IX, Sensengasse 2, Austria.

THE MENNINGER FOUNDATION.—Dr. S. I. Hayakawa, internationally noted semanticist, has been appointed an Alfred P. Sloan Visiting Professor in the Menninger School of Psychiatry at Topeka, Kansas. He will serve for about three months from mid-January 1961.

Dr. Hayakawa is professor of language arts at San Francisco (Calif.) State College and is editor of *ETC.*, a quarterly review of general semantics published by the International Society for General Semantics. He has held visiting professorships at Columbia University Teachers College, the University of Notre Dame, and the University of Hawaii.

In 1959 he was awarded the Claude Bernard Medal for Experimental Medicine and Surgery by the University of Montreal, the only non-physician to have been so honored.

AMERICAN ORTHOPSYCHIATRIC ASSOCIATION.—The 38th annual meeting of the American Orthopsychiatric Association will be held at the Hotel Statler-Hilton, New York City, March 22-25, 1961. William S. Langford, M.D., professor of psychiatry at

Columbia University will deliver the presidential address on adaptation of the child in the pediatric hospital to illness and hospitalization. René Dubos, Ph.D., professor at the Rockefeller Institute, will also speak on problems of biological adaptations of children to modern society.

Further information is available from Marion F. Langer, Ph.D., American Orthopsychiatric Association, 1790 Broadway, New York 19, N. Y.

ANIMAL STUDY IN PUBLIC SCHOOLS.—The National Society for Medical Research reports: Five states—Illinois, Maine, Massachusetts, Oklahoma and Washington have laws to prohibit all or nearly all study of animals in public schools, while Pennsylvania has a wise law prohibiting only *cruel* experiments.

The perennially busy Antivivisectionists seek to extend the ban to all animal studies and have contacted local school authorities to that end, in many cases even securing pledges that no more studies involving live animals will be allowed.

As the Society for Medical Research points out, no science is well taught unless the real subject matter is studied directly, and that the study of animals is basic to education in biology and should be limited only by reasonable humane restrictions.

AWARD TO DR. NOLAN LEWIS.—The first Emil Guthell, M.D. Memorial Medal for Outstanding Contributions to Psychotherapy was awarded to Nolan D. C. Lewis, M.D. by the Association for the Advancement of Psychotherapy on Oct. 30, 1960.

At the Memorial Conference Dr. Lewis gave a conservative and comprehensive discussion of the future of psychotherapy, in which he urged the adoption of higher professional standards and more scientific methods in the application of this method of treatment, and the avoidance of sectarianism—he stressed the common denominator that must underlie all forms of psychotherapy, and the importance of suggestion inherent in the doctor-patient relationship.

PSYCHIATRISTS AND MILITARY SERVICE.—It is now possible for physically profes-

sionally trained qualified psychiatrists to meet their military obligations while assigned to the staff of Saint Elizabeths Hospital.

For further information and application forms write Dr. Winfred Overholser, Saint Elizabeths Hospital, Washington 20, D. C.

SOVIET CONTRACT WITH N. Y. SCIENTIFIC PUBLISHER.—Consultants Bureau, publishing house in New York, has, from 1946, pioneered cover-to-cover translation of Soviet scientific journals. By 1955, five Soviet scientific journals were being published by the company. The following year, the company entered into contracts with the American Institute of Physics and the American Institute of Biological Sciences to provide translation of 5 additional Russian scientific journals.

In June 1960, a contract covering the complete translation into English of 23 major Soviet scientific and technical journals was renewed with Mezhdunarodnaya Kniga, the official Soviet international book agency.

In Moscow a new contract establishing terms for exclusive English language rights to Soviet scientific books for the next 6 years was signed by Consultants Bureau and Mezhdunarodnaya Kniga, October 1960. All books published by Consultants Bureau will in future be made available to English-speaking scientists within 6 months of their publication in the U.S.S.R. Where the importance of Soviet conferences warrants speedier dissemination of their proceedings, English translations will be published at the same time as the Russian originals appear. Every book chosen for translation into English will have the recommendation of both Soviet and American scientists as being an outstanding contribution to the existing literature on the subject.

DR. KETY HEADS PSYCHIATRY AT JOHNS HOPKINS.—Dr. Milton S. Eisenhower, president of Johns Hopkins University, and Dr. Russell A. Nelson, director of the Johns Hopkins Hospital, have jointly announced the appointment of Dr. Seymour S. Kety as professor and head of the department of psychiatry at the Johns Hopkins University School of Medicine and psychiatrist-in-chief

of the Johns Hopkins Hospital. Dr. Kety succeeds Dr. John C. Whitehorn who retired June 30, 1960.

A graduate in medicine from the University of Pennsylvania, Dr. Kety joined the department of pharmacology at that University in 1943 and in 1948 became professor of clinical physiology in the graduate school of medicine. Since 1951 he has been associated with the National Institutes of Mental Health and Neurological Diseases and Blindness at Bethesda, Md. Since 1956 he has been chief of the laboratory of clinical science of the National Institute of Mental Health.

The Johns Hopkins University is fortunate in securing the services of this distinguished research scientist.

MENTAL HOSPITAL INSTITUTE FOR COMMUNITY PHYSICIANS, MARYLAND.—Family physicians across the State are invited to attend Maryland's first Mental Hospital Institute for Community Physicians to be held Mar. 1 to Apr. 5, at Spring Grove State Hospital in Catonsville.

The Institute will be held on 5 successive Wednesdays from 2 to 5 p.m. under the joint auspices of Spring Grove, the Maryland Academy of General Practice, the Psychiatric Institute of the University Hospital of Maryland, and the Baltimore Psychoanalytic Institute. Dr. Bruno Radaukas, Superintendent of the Hospital is Chairman of the Planning Committee.

Further information may be obtained from Dr. Radaukas at the Spring Grove State Hospital, Catonsville, Md. Registration will be limited to the first 50 applicants.

DR. ANTHONY JOINS CHICAGO INSTITUTE FOR PSYCHOANALYSIS.—E. James Anthony, M.D., of St. Louis, Mo., graduate of King's College, London, and a former Nuffield Fellow in Child Development at the University of Geneva, where he worked with Dr. Piaget, has been appointed to the faculty of the Chicago Institute for Psychoanalysis.

Dr. Anthony came to the United States in 1958 as Ittleson Professor of Child Psychiatry at the Washington University in St. Louis, and has been serving as head of

Child Psychiatry at the Jewish Hospital in that city.

ANNUAL INSTITUTE IN PSYCHIATRY AND NEUROLOGY, LITTLE ROCK, ARK.—The Thirteenth Annual Institute in Psychiatry and Neurology will be held on March 2 and 3, 1961, at the North Little Rock Division of the Consolidated Veterans Administration Hospital, Little Rock, Ark. There will be three related conferences on March 1 on Clinical Psychology, Psychiatric Social Work, and Psychiatric Nursing.

There is a dinner meeting planned for Thursday evening, March 2, with Dr. Robert H. Felix, President of the American Psychiatric Association, as guest speaker.

Further information may be obtained from Dr. H. W. Sterling, Manager, Veterans Administration Consolidated Hospital, Little Rock, Ark.

THIRTY-EIGHTH ANNUAL MEETING OF THE AMERICAN ORTHOPSYCHIATRIC ASSOCIATION.—This meeting will be held from March 23 to 25, 1961, at the Statler Hilton Hotel in New York City.

By arrangement with the Professional Placement Center of the New York State Employment Service, placement services will be provided during the annual meeting. The Placement Area will be on the Exposition Floor of the Statler Hilton Hotel.

Advance registration is required by everyone including members of the American Orthopsychiatric Association. Registration fee for non-members is \$9 for 3 days; \$4 for a single day. Pre-registration in workshop(s) and/or panel(s) is also required. For registration and further information write: Executive Secretary, American Orthopsychiatric Association, 1790 Broadway, New York 19, N. Y.

TRAINING PROGRAM AT THE SILVER HILL FOUNDATION.—This is a 3-year training program carried on in cooperation with the Columbia-Presbyterian Medical Center in New York. The first year of training is spent at that Medical Center and the second and third years at the Silver Hill Foundation in New Canaan, Conn. At present only 2 or 3 residents are accepted annually for training.

All stipends are without maintenance; the stipend for first year residents is \$4,000 per year, for second year residents \$7,000 and for third year residents \$8,000.

For further information write: Dr. William B. Terhune, Medical Director, Silver Hill Foundation, Valley Road, New Canaan, Conn.

TWO WORKSHOP SEMINARS IN THE RORSACH TEST.—The Department of Psychology at the University of Chicago is offering 2 workshop seminars in the Rorsach Test.

The first, June 19-23, 1961, will be about the foundations of the test. The second, June 26-30, will discuss advanced clinical interpretation. Dr. J. S. Beck will conduct both seminars.

For information write to: Rorsach Workshops, Department of Psychology, University of Chicago, Chicago 37, Ill.

PSYCHOTHERAPY WEEK AT LINDAU (BODENSEE).—Under the direction of Dr. Helmut Stolze, this training period is from May 1-6, 1961, followed by a second week, May 8-13, for practical experience. This training program is sponsored by the Medical Society for Psychotherapy in Lindau.

Further information may be obtained from The Secretariat of the Lindau Psychotherapy Week, Dienerstrasse 17, München 2, Germany.

JAMES N. BURROWS APPOINTED DIRECTOR OF INSTITUTE FOR CRIPPLED AND DISABLED.—Mr. Burrows, who received an M.A. degree from Miami University, Oxford, Ohio and a B.Sc. degree from the University of Cincinnati, has been appointed Director of the Institute for the Crippled and Disabled, 23rd St. at 1st Ave., New York City. For the past 20 years Mr. Burrows has been engaged in the management and administration of government and private rehabilitation and medical programs.

PSYCHIATRIC EDUCATION FOR GENERAL MEDICAL PRACTITIONERS.—To meet a growing demand from physicians in the field of general medicine for instruction in dealing with psychiatric problems encountered in

their regular work, a plan to meet the situation in New York State is being developed jointly by the Department of Mental Hygiene, and the New York State branches of the American Psychiatric Association with the cooperation of the New York State Medical Society.

It is presumed that the proposed courses will be so organized as to receive approval for Category 1 credit by the American Academy of General Practice.

THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The following were certified in Child Psychiatry in December, 1960:

Ackerly, S. Spafford, M.D., Louisville, Ky.
Chamberlain, Herbert E., A.B., M.D., Sacramento, Cal.
Dawes, Lydia Gibson, B.S., M.D., Cambridge, Mass.
Drewry, Henry Harris, B.S., M.D., D.Med.Sc., Woodside, Queens, N. Y.
Farrell, Malcolm Joseph, B.S., M.D., Waverley, Mass.
Fries, Margaret E., M.D., New York, N. Y.
Kessler, Edwin S., M.D., Washington, D. C.
Kesrenberg, Judith S., M.D., New York, N. Y.
Koff, Robert, M.D., Chicago, Ill.
Little, Harry Morrow, M.D., Houston, Tex.
Martin, Katharine Hawley, M.D., M.P.H., Watertown, Conn.
Rich, Gilbert Joseph, Ph.D., M.D., Roanoke, Va.
Schroeder, Paul L., B.S., M.D., Atlanta, Ga.
Simson, Clyde B., M.D., Detroit, Mich.
Solomon, Joseph C., A.B., M.D., San Francisco, Cal.
Sperling, Melitta, M.D., New York, N. Y.
Staples, Herman D., M.D., Media, Pa.
Waterman, John Howard, B.Sc., A.B., M.D., Portland, Ore.

STATEMENT TO THE AMERICAN BOARD OF PEDIATRICS AND THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY.—The increasing interest of potential candidates in the field of Pediatric Neurology challenges the 2 American Boards most concerned to determine guide-lines for program directors in Pediatrics and Neurology and for potential candidates in these disciplines. The Committees on Child Neurology of the American Board of Pediatrics and the American Board of Psychiatry and Neurology met on September 21, 1959, and October 21, 1960, and submit to their respective Boards the following statement: Recommendations for a desirable training program in Pediatric Neurology:

1. A year of approved internship.
2. Approved residency training in a pediatric service, sufficient to meet established requirements of the American Board of Pediatrics.
3. Two years of residency training in General Neurology, including the basic neurological sciences, and under conditions consistent with es-

tablished requirements of the American Board of Psychiatry and Neurology.

4. A year of residency training in a pediatric neurology service meeting the established requirements of the American Board of Psychiatry and Neurology.

Flexibility should be allowed in the order in which these components of the training program are taken.

Training Program Facilities :

1. The pediatric neurology service should be in the setting of an active pediatric service with a sufficient number of beds for the number of residents in training and an active outpatient department. It is also recommended that there be opportunities for the trainee to study the newborn and that he also have opportunity to maintain continuing contact with patients in this category.

2. The pediatric neurology service should be under qualified neurological direction.

3. Patient beds assigned to the pediatric neurology service should preferably be in close physical contact with the pediatric service and under independent pediatric neurologic direction.

4. The pediatric neurology resident should have responsibility under competent supervision for patient care.

5. It is also desirable that the pediatric neurology program be in a setting in which basic neurological science contacts are readily available.

The adoption of these recommendations might serve as a preliminary step toward further consideration of a formalized subspecialty Board in Pediatric Neurology.

THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The following were certified at New York, N. Y., December 10, 12 and 13, 1960 :

BOOK REVIEWS

AMERICANS VIEW THEIR MENTAL HEALTH.

By Gerald Gurin, Joseph Veroff and Sheila Feld. Monograph Series No. 4, Joint Commission on Mental Illness and Health. (New York: Basic Books Inc., 1960, pp. 444. \$7.50.)

Many attempts have been made recently to survey the extent and seriousness of mental and emotional disabilities among the American people. Other studies have been aimed at measuring the extent and quality of public understanding of mental illness. Still others have tried—usually without striking success—to arrive at a generally acceptable definition of mental health. The present study claims to be unique in that it is an effort, elaborate and comprehensive in conception, to gather information on what the American people think, subjectively, about their own mental health.

A basic assumption in this study, as with others undertaken by the Joint Commission, is that every person from time to time will experience psychological trouble. He will cope with this with varying degrees of success, by his own efforts or with help from someone else. Thus "mental health springs not from avoiding all stress . . . but from a capacity to accept normal amounts of stress with some ability to rebound."

These are surely vague, relative and shifting elements to appraise, whether in oneself or in others. After all, how much is a "normal" amount of stress and how can one measure "degrees" of successful coping? But the attempt to study how people rate *themselves* in this regard is defended on the grounds that "the needs of people—as they themselves feel them . . . and express them—ultimately determine the ways in which organized efforts will be made to meet these needs."

The study was conducted by the University of Michigan Survey Research Center. Well-established techniques, based on the probability sampling methods used in public opinion polls, were used. The sample population comprised 2,460 adults living at home, selected according to the usual demographic indices, (age, sex, education, income, occupation, place of residence, etc.) so that it was truly representative of the national population. The data were collected by trained interviewers who followed a carefully designed and tested questionnaire. Interviews were lengthy, averaging about 2 hours each. The resulting information was coded, and analysed according to modern

statistical methods.

In general two kinds of questions were asked. The first dealt with people's adjustment to life, whether they were happy or unhappy, worried or unworried, and their attitudes toward marriage, parenthood and work. The second kind of question dealt with what they do about their problems, what help they seem to need and from whom.

Whether "happiness" as judged subjectively has much to do with a person's mental health or not may be debated. Nevertheless the study showed that 89% of American people are either "very happy" or "pretty happy." The commonest sources of such desirable feeling were evenly divided between economic and material sufficiency on the one hand and children in the family on the other. Interestingly enough, relatively few people—about 4%—were worried or made unhappy by fear of international catastrophe, atom bombs and so on. In spite of the high incidence of happiness as reported in this survey, about 25% of the sample admitted that they worried "a lot" or "all the time." And about 20% felt that they had been close to a "nervous breakdown" at some time. Nearly 1 in 4 admitted having had personal problems sufficiently serious to warrant consultation with a professional person, but only 1 in 7 actually did so. Forty-two percent of these consulted clergymen, 29% physicians, 18% psychiatrists or psychologists and 10% social agencies of one kind or another. Of those seeking such help, 58% felt that they were definitely helped.

There is little evidence to support the idea that many people with troubles talk them out with the bar-tender, the taxi-driver or the fortune-teller. However, many do talk about their problems with their spouses, members of their family or their friends.

Dr. Ewalt, Director of the Joint Commission, believes that this study is probably the first piece of convincing evidence that public education in mental health principles has increased general understanding of the human mind and has led to a greater recognition of the psychological nature of many problems. This is particularly evident in the younger and better educated groups.

The study will obviously be of great interest to those concerned with public education, public information and the general epidemiology in the field of mental health and illness.

A PHARMACOLOGIC APPROACH TO THE STUDY OF THE MIND. Edited by Robert Featherstone and Alexander Simon. (Springfield, Ill.: Chas. C Thomas, pp. 397. \$10.75.)

The enormity of information given to us in the 12 printed pages comprising Aldous Huxley's contribution to this volume, is quite unbelievable. He shows us how this volume really comprises 41 books which we all need to read if we are to practice a modern 1960 brand psychiatry, since each man who presented a paper at the symposium at the University of California could have produced a book on his topic. However, each was compelled to concentrate into a minute volume all his facts for presentation to this congress of scientists.

Thus, in much the same manner that Huxley uses to make his point about "Hedgehog" (condensed) science versus "Fox" (all encompassing) science, one can envisage this book as a collection of hedgehog condensations or capsules (poems) of knowledge in this new frontier for psychiatric expansion.

It is indeed exciting (after 35 years in psychiatry) to read Joel Elkes' scholarly presentation of how far we have gone already in "Some Points of Reference in Psychopharmacology," when we still think of this field as so new and unexplored in psychiatry; and "The Effects of Drugs . . . on the Energy Metabolism of the Brain" by Seymour Kety; and Sidney Udenfriend's brief on "Psycho Chemistry" wherein he points out that, "Within recent years it was shown that Iproniazid . . . could indeed interfere with serotonin and noradrenalin metabolism" and "We have found a remarkable agreement between the dosages worked out by psychiatrists, through trial and error, and the dosages needed for maximal inhibition of mono amine oxidase in man."

Then President Malamud's final comment in his discussion of "A Clinical Approach to Mental Disease": "To the clinician this is very exciting . . . and highly promising in spite of occasional controversy. The pragmatically oriented medical practitioner will do well to maintain an objective attitude" (while developments continue in this field).

The most unsophisticated novice in the field of biological chemistry will realize from a casual reading of Albert Zeller's succinct chapter, "The Concept of Enzymes . . .," the inescapably intimate relationship of the enzymes to this new and most fruitful field of research. The romantic description of his years of slow painstaking delving into this new biochemical frontier cannot fail to whet the appetites of investigative minds, with the realization that

better than platinum or uranium equivalents in the knowledge of human disease lie in the revelations to come, to the researcher who can fathom the depths of this exceedingly complex wilderness of biological chemistry.

This book makes a most interesting new departure by presenting 6 pages of candid camera photos of the various authors.

All those who listened intently as Ralph Gerard delivered his Academic Lecture to all APA listeners only a few years ago, will want to peruse his further thoughts at this time.

Nothing is available in the literature to equal Nathan Kline's exhaustive survey of the current literature concerning "Therapy with Psychic Energizers" plus his own invaluable comments in this field which he pioneered with his collaborators. This chapter alone is worth the price of the book.

In his excellent summarization consisting of 5 printed lines, Dr. John B. Saunders, Dean of the California School of Medicine, wisely advises the reading of Dr. John C. Saunders' chapter "Psychic Energizers: A Source of Psychopharmacological Theories"—an astute capsular summarization indeed, and a gem of scientific effluence.

Many equally worthy chapters are not mentioned here purely because of space restrictions. But I believe there is no more essential book for every psychiatrist to possess than this—and likewise for every internist or other physician using modern chemotherapy for psychiatric illness, the book is a *must*!

The only obvious defect I encountered in reading this book was the absence of any statement by any of the many authors, stressing the need for keeping accurate data on blood transaminase findings in all cases being administered energizer chemotherapy. It would be most unfortunate if this observation, which I have stressed in a number of papers, was ignored by the vast body of clinicians who are administering the various antidepressant chemicals in ever increasing quantities today. The warning sounded by discovery of an elevated SGO-T or SGP-T which results in prompt interruption of the medication, or sharp reduction in dosage, has undoubtedly saved many doctors from serious embarrassment that might have developed if serious side effects had developed. Especially in these early days when the groundwork is being built for the psychopharmacology of tomorrow, and perhaps for years to come, the clinician needs to be fully informed regarding every laboratory or other adjunct that will increase his skill and also will enhance the safety of his patient.

I shall consider it one of the major additions

to my library wherein Freud's Collected Papers were considered the major indispensable item 30 years ago, and Menninger's various volumes some years later.

Montclair, N. J.

AN MMPI CODEBOOK FOR COUNSELORS. By L. E. Drake and E. R. Oetting. (Minneapolis: University of Minnesota Press, 1959, pp. 140. \$3.75.)

The authors have produced a very useful manual for the counselor of the normal, young adult. Based on research conducted between 1945 and 1957 with over 4,000 students who were counseled at the University of Wisconsin, personality characteristics associated with various MMPI profiles are presented.

Introductory sections present a thoughtful approach for the use of psychometric data in counseling, and discuss the research from which the codebook was developed.

BERNARD LUBIN, Ph.D.,

LE RAZZE E I POPOLI DELLA TERRA. Edited by Renato Biasutti. 4 vols., 3rd ed. (Turin, Italy: Unione Tipografico-Editrice Torinese, 1959. Lire: 36,500.)

There is nothing like these four anthropological volumes in any language. They cover the whole world of mankind from the beginning of his history down to the present time in all the wide variety of his different phases, both physically and culturally. There are literally thousands of illustrations, many in full color, maps, tables, and extremely readable discussions of man's psychological, physical, and cultural traits. The various sections are written by Italian experts in the fields in which they write, and the appeal of these volumes is to the general reader as well as the student. The bibliographies and author and subject indexes are excellent, and altogether these are most admirable volumes which will long serve the most useful purpose of emphasizing the fact that the proper study of mankind is man.

Princeton, N. J.

THE DANCE. By Joost A. M. Meerloo. (Philadelphia & New York: Chilton Co., 1960, pp. 152. \$4.95.)

The pictures in this book are worth the price of the book. Of the text by Dr. Joost A. M. Meerloo the less said the better, for it was obviously written without any recourse to authoritative sources, and is entirely lacking in

those dimensions of understanding which only the anthropologist can provide. The subject is an important one, and therefore it is good to have this book for, even though it be textually inadequate, it is so continuously the source of disagreement and doubt that it will give the reader furiously to think. It would not be unfair to Dr. Meerloo to cite some of his typical opacities in view of the fact that his brief text and comments are so bestrewn with them—but I shall refrain. As I have said, the pictures make the book very worth while—the banality of the text cannot detract from them. Those who are interested will find both interesting.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

THE OPEN AND CLOSED MIND. By Milton Rokeach. (New York: Basic Books, 1960, pp. 447. \$7.50.)

This rather well produced book reports in detail the results of a series of studies carried out by Rokeach and his students in pursuit of the measurement and the correlates of "dogmatism" and "opinionation." Their work is essentially and confessedly a derivation from the well known studies on the authoritarian personality. As many critics had pointed out, authoritarianism in the original work was entirely right-wing or Fascist authoritarianism; Rokeach has tried to redress the balance by concerning himself with dogmatic and opinionated personalities such as might be found right, left and centre, and indeed, in many fields quite unrelated to politics. Two scales entitled "Dogmatism" and "Opinionation" were accordingly constructed and shown to be reasonably reliable and not highly correlated with radical or conservative views. These scales were administered to many different groups in the United States as well as to some small British samples. The results are presented in a context of theorising so prolix, and at the same time so woolly, as to defy a brief summary.

Some of the results are of psychological interest, particularly those in which the author has tried to relate scores on his scales to the subject's method of attack on certain experimental problems. There are, however, a number of criticisms which have to be made and which very much reduce the acceptability of his conclusions. In recent years the authoritarian studies have been severely criticized because no attention was paid to the problem of "response set," i.e., the tendency of people to endorse certain types of responses irrespective of the content of the question. There is ample evidence for the existence of such sets and their relevance to work of this kind, yet they

are only mentioned very briefly and inadequately at the end of the book and the writer is forced to conclude that unless the proper analysis of such response sets is carried out "... we will not be able to tell for sure, what role 'response set' has played in our research." The reader may justly wonder why such a simple and crucial experiment was not done, and how he can be expected to interpret data which, in the author's own view, apparently cannot be interpreted.

Other doubts arise with respect to the statistical treatment of the data which is, at best, uninspired and, at worst, unacceptable. As an example of the writer's uninspired way of treating the data we may mention the fact that no where is Multiple Discriminant Function Analysis used, although several of the experiments cry out for something a little more sophisticated than simple t tests. As an example of the unacceptable, consider Table 19.8 in which means are given for three groups of the age at which bedwetting stopped. The mean age for the dogmatic group turns out to be 6.2; that of the non-dogmatic group, 2.2. This looks interesting until it is realised that of the 25 people in the non-dogmatic group, 21 replied that they did not remember, and that the author quite arbitrarily assumed that this reply could be set as equal to two years for the purpose of establishing the mean age! The difference between the groups, therefore, is produced entirely by this purely arbitrary decision for which no rationale is given. This table will for evermore become a cherished part of my lecture on the abuses of statistics, given every year to incoming students.

The book as it stands cannot, for the reasons given, be considered a notable contribution to social psychology. If the author had taken seriously his responsibilities to solve the problem of "response set" as applied to his scales, and had got a statistician to go over his tables, the resulting book might have been interesting or even important. It seems a pity that the urge to publish was apparently too strong to make it possible for him to undertake these small additional chores.

LIFE AGAINST DEATH. By Norman O. Brown.
(Middletown, Conn. : Wesleyan University Press, 1959, pp. 366. \$6.50.)

THIS is a book that links Freud's death instinct concept with religion, with man's destructiveness, and with his need for salvation.

The psychiatrist is apt to encounter it when his patient enters, anxious and trembly, and demands an answer to Dr. Brown's apparently telling logic. The fact that all of these topics are speculative, to say the least, is overlooked by the author and is apt to be overlooked by the easily misinformed layman. Evidently Dr. Brown has encountered Freud rather late in life and embraces him with a passion and uncriticalness of a middle-aged fling at romance.

The cornerstone on which this book is erected is the psychoanalytic concept of repression. Once having shown it to be a bad thing and having documented man's many woes caused by his repressive tendencies, the author's next obvious step is: what is the way out? Here in a brief, final chapter, we are given the old concept of redemption through expiation dressed in a modern, existentialistic frame. On the way to this denouement, there are many unsettling passages including the statement that the whole human race is neurotic and quotes from philosophers from Plato to Whitehead, bent a bit to fit the author's thesis. Yet this is obviously a sincere book and being critical of Dr. Brown's efforts makes me as guilty as punching holes in CARE packages. Yet a book like this can cause a good deal of alarm because it is a serious well-intended effort and this stamp is easily mistaken for veracity. I note my copy is the third printing so I must assume that attempts to join psychoanalysis and religion into a palatable gruel is still quite popular. There have been many more dispassionate and less passionate attempts than the volume under consideration.

DON D. JACKSON, M.D.,
Palo Alto, Calif.

DISEASES OF THE NERVOUS SYSTEM IN INFANCY, CHILDHOOD AND ADOLESCENCE. By Frank Ford. (Springfield, Ill. : Charles C Thomas, 1959, pp. 1548. \$29.50.)

Doctor Ford, in his fourth edition on pediatric neurology, has maintained the high quality of this concise encyclopedic reference volume. The author has fully justified the additional 350 pages in the new edition (1,548 pages as compared with the 1,181 of the 3rd edition) in meeting the important advances of pediatric neurology since 1952. Chapter I of the previous edition on "The Examination of the Nervous System" has been omitted. Some might believe that the author could have more appropriately omitted the section on neuro-anatomy or cut back on some of the other chapters so as to have included the recognized important chapter on Examination. On the other hand,

because of the important advances that have been and are being made in neuro-anatomy and neuro-physiology and their increasing clinical contribution to pediatric neurology, this reviewer believes the author can justify deleting the chapter on Pediatric Neurological Examination, available in other textbooks on child neurology and which do not serve the encyclopedic and extensive reference book purpose singly covered by this book.

The edition brings up to date the new advances in the prevention and treatment of neurological disorders as, for example, the Salk vaccine for prevention of poliomyelitis and several additional drugs now available in the treatment of tuberculous meningitis in addition to the one streptomycin mentioned in the 3rd edition and the more recent drugs for the control of the epileptic disorders. Many advances in the diagnosis and treatment of neurological disorders in infancy and childhood are apparent in the chapter on toxic and metabolic disorders enlarged from 155 in the 3rd edition to 225 pages in the current edition. This includes such new subjects as disorders of protein metabolism, familial amyloidosis and the different forms of cerebral sclerosis. There are additional practical subjects on insect, snake and fish bites.

The author's chapter on "Psychogenic Disorders Simulating Organic Disease of the Nervous System" could be expanded into the field of neurology of behavior in the light of our contemporary advances in the structure and function of the nervous system between relating behavior to the nervous system, particularly with respect to the rapidly maturing brain of the infant and child. Perhaps the author in a future edition may well require 2 volumes to include the deleted chapter on the neurological examination and extending the chapter on psychogenic disorders into a discussion of behavior disorders of the infant and child and their relation to neurology.

This reviewer concludes that there is currently no book in pediatric neurology which so ably and comprehensively covers this subject, in addition to being an excellent reference book on the subject. It continues an essential library tool to all neurologists and to pediatricians interested in the neurological disorders of infants and children. As a child's behavior symptoms and signs may require the differential consideration of neurological and/or environmental etiological factors, this book has an essential place in the library of child psychiatrists.

KNOX H. FINLEY, M.D.,
Presbyterian Med. Center,
San Francisco, Calif.

BEHAVIOR AND PHYSIQUE. By R. W. Parnell, M.A., D.M. (Baltimore, Md.: Williams and Wilkins, 1958, pp. 134. \$7.00.)

This may be a difficult book for the average American psychiatrist to read, perhaps because of his relatively limited knowledge of or interest in constitutional aspects of psychiatry. The author's method of somatometry is closely related to that of Sheldon's and can be viewed in some respects as an extension of the latter. As such the author deals relatively briefly with Sheldon's methods as an introduction to his own. If his American readers are not sufficiently acquainted with the concepts and descriptive devices utilized by Sheldon, they may find themselves burdened with the task of having to learn about 2 methods, the understanding of the second of which is dependent upon familiarity with the first. The author's style of writing is concise, concentrated, and demanding of the reader's attention at all times. Furthermore, the author has a curious predilection for combining a summary with some discussion of topics previously unmentioned. Nevertheless, for those who are interested in its subject matter, this book is a worthwhile addition to a library.

In the matter of estimating somatotype, the author states his aim as "giving an index that will remain constant throughout life," despite the variation in measurements and proportions occurring in different age periods. He does not claim to have achieved this aim nor is he even sure that it is achievable. His methods consist of physical anthropometry in conjunction with photography. His shorthand descriptive system is simpler than that of Sheldon; he utilizes the terms fat, muscularity, linearity as the 3 essential somatic components. Furthermore, he includes only 2 of these in his actual description of individuals, with the dominant component coming first and placed in capitals (i.e., F1 or Lf, depending on which is dominant). He has studied a relatively large number of individuals and takes up the questions of civil state, variety of human matings, fertility, sex ratio of children, academic performance, selection of occupation, and susceptibility of individuals to mental illness at various ages, all with reference to somatotype. For example, in his series, Mf types form the most stable group in both sexes. Lf types are most disposed to breakdown before 25 years of age, whereas Lm types are the most susceptible from 25-34. The Lf type, along with F1 in women and Lm in men, is found in a large proportion of younger schizophrenic patients. Lf men are found to do well academically despite their susceptibility to emotional disturbance.

The author suggests that somatometry may become a useful adjunct to other methods of clinical observations. To this reader the book was stimulating if only because it brought into focus the ~~extent~~ to which ~~the~~ ~~entire~~ subject appears to be neglected by American psychiatrists. It is entirely possible that with the increasing interest in constitutional and biological aspects of psychiatric illness this situation may change. At the moment, the book must be recommended as a thoughtful and scholarly work, tentative in its conclusion, and of special interest to those who tend to consider the constitutional as well as the psychological aspects of emotional disorder.

The New York Hosp.,
New York 21, N. Y.

MENTAL DEFICIENCY. Edited by Ann M. Clarke and A. D. B. Clarke. (Glencoe: The Free Press, pp. 513. \$10.00.)

This book is a collection of 18 papers, organized and edited in such a fashion that it can serve as a basic reference book on mental deficiency. Most of the authors are British psychologists, and the book is written primarily for psychologists. After presenting their basic considerations and some epidemiological data, they describe the theoretical and practical problems in the clinical field. The book has 3 aims: to summarize the literature on the psychological and social aspects of mental deficiency against the background of genetics and neuropathology; to show the intimate and reciprocal relationship between theory and practice, together with the use of experimental methods in both areas; and to indicate in a practical manner how the learning defects and social problems posed by the subnormal may be ameliorated.

There are few comprehensive books on mental deficiency. Some written by physicians, for physicians, emphasize the medical aspects. To psychiatric readers, acquainted with these publications, the present book will serve as a guide on the psychological, educational, and sociological problems of the field. They will likely find the information pertaining to medicine quite limited and somewhat out-of-date, particularly that relating to the etiology of mental defect and to the methods of biological treatment. Present-day treatment of such conditions as phenylketonuria and galactosemia, and the use of psychopharmacological agents and other drugs, are described quite briefly. However, several very excellent chapters will adequately compensate the reader for this lack.

Each chapter on different aspects of this subject summarizes the pertinent literature, together with critical comments on the articles reviewed. These discussions give an excellent historical account particularly of the work of psychologists and sociologists. The lack of factual information is repeatedly emphasized, with some suggestions for desirable research approaches.

This reviewer was particularly impressed with the discussion of some topics; for instance, the brief section of pseudo-feeble-mindedness clarifies many issues of diagnosis and prognosis. The authors emphasize that "pseudo-feeble-mindedness" involves mistaken prognosis, rather than diagnosis. Equally good is the chapter on learning and mental defect, in which clear differentiation is made between the broad clinical syndrome of mental defect and the deficit in learning ability. The excellent chapters on brain damage and cerebral palsy discuss these syndromes and their relationship to intellectual impairment.

Part III on "Practical Problems" describes many of the issues encountered in the daily clinical practice with the mentally deficient. The comments are applicable to private practitioners, to those in public institutions, or in school settings. The chapter on speech disorders—the most common handicap in the mentally deficient population—classifies these conditions by etiology and describes speech therapy and other corrective techniques in simple, easily readable language.

A considerable amount of scientific information is combined with practical suggestions. The book conveys the personal warmth the authors feel toward the deficient patient and reflects years of experience in research and in clinical work in close collaboration with physicians. It conveys the authors' optimistic outlook toward the problems of mental deficiency; a sense of worthwhileness of professional investment in therapeutic endeavors; and an image of good social prognosis, particularly for the mildly defective individual. Clinicians will appreciate this overtone.

The book should be an excellent addition to the library of any psychiatric institution, or to any facility dealing with problems of mental deficiency. It should serve as a good reference book for practicing psychiatrists who want to become acquainted with this major psychiatric problem. It should be required introductory reading for clinical psychologists starting work with the mentally deficient.

GEORGE TARJAN, M.D.,
Pacific State Hosp.,
Pomona, Calif.

A COMPARATIVE STUDY OF ANTIDEPRESSANTS IN
BALANCED THERAPYDAVID C. ENGLISH, M.S., M.D.¹

This report is part of a larger comparison study of approximately 1,800 private psychiatric patients. Iproniazid² (INZ) was employed in 180 patients, 228 patients were treated with phenelzine,³ 86 with imipramine,⁴ 62 with nialamide,⁵ 71 with phenylcyclopropylamine,⁶ 51 with deanol,⁷ 59 with benactyzine-meprobamate,⁸ 842 with electroconvulsive therapy, 195 with isocarboxazid (ICZ),⁹ and 32 with a combination of ICZ and INZ to further expedite recovery. In a previous paper⁽¹⁾, the author reported both clinical results and side effects with 223 patients treated with INZ, the parent drug of which ICZ is an analog. In that 18-month series, discontinuance of INZ was never required and edema in 3 cases was the only side effect noted. The INZ series consisted primarily of inpatients; at that time no effective means of treatment of moderately severe depression was known other than ECT, and there were natural reservations about trying drugs alone on an outpatient basis. ICZ results in agitated depressives were so good that routine outpatient treatment became feasible.

Clinical results in patients with depressive and acute schizophrenic reactions treated with ICZ have shown it to equal ECT, to usually initiate improvement within 3 to 7 days and to have no serious and few minor side effects. The median INZ patient showed a considerable improvement in 26 days; with ECT alone there was improvement in 22 days; in contrast, the ICZ pa-

tient exhibited a 50% reduction of symptoms in 10 days. Because of the greater rapidity of action of ICZ, it was possible to treat over half of this series on an outpatient basis, with no hospital facilities being required other than laboratory studies done biweekly as an extra precaution.

The author has previously shown that combined INZ and tranquilizing drugs, such as chlorpromazine¹⁰ or mepazine,¹¹ in simultaneous medication ("up down drugs") maintained control in agitated depressives during their rehabilitation⁽¹⁾. The combination with tranquilizers permitted treatment of acute schizophrenics who became too combative on antidepressants alone. INZ premedication reduced necessary ECT's by 1/3 (2-3). Combinations of tranquilizing drugs (chlorpromazine-mepazine⁽⁴⁾, chlorpromazine-prochlorperazine⁽¹²⁾ (1, 5), have shown additive therapeutic effects with no increase in side effects. The present paper shows that the more rapidly acting ICZ was even more effective than INZ in depressed patients, and that ICZ with INZ (32 cases) produced fewer minor ("nuisance") side effects than equivalent amounts of either alone. The "balancing" of simultaneous antidepressants, in turn balanced against 1 or 2 tranquilizing drugs, provides the first means of predictably expediting private patient therapy without ECT. Comparative results with the various antidepressants used are shown in Table 1.

The author prefers to call this approach "balanced therapy" as opposed to the so-called "broad-spectrum therapy" (6). "Balanced therapy" consists of using all relevant therapies from the beginning, with inter-views, drugs, and (occasionally) ECT or

FIGURE 1

hospitalization initially combined, the types and amounts depending upon the patient's needs and his environment. Drugs and ECT are not used as "additional physiodynamic levers" in patients subsequently found resistant to psychotherapy(6) nor is this "shotgun therapy," since each agent has a predetermined role. With experience, drug changes based on "balancing" action produce the expected result more accurately than do single drugs alone. Here a change in one drug almost always requires a corresponding change in at least one other. The different therapeutic factors can be synergistic only if complete flexibility is maintained, the quantity and variety of each treatment component being necessarily partially governed by the others and different for every patient.

Figure 1 represents a schematization of "balanced" drug therapy according to the clinical course of depression; the sample curve shows the effect of reducing the ICZ dosage 1 to 2 days too soon, and then, to make sure that the patient maintains recovery, carrying it too high for 2 extra days. This type of chart has been found helpful in explaining to patients the type of illness, the rationale of the drugs, and the progress achieved with them.

The relatively new class of amine oxidase inhibitors produced remarkable results when correctly used. ICZ is emphasized because it is both the newest and most effective as judged from results in studies with 8 such drugs and ECT in approximately 1,800 private patients with placebo controls. No attempt is made to say that ICZ is a "cure-all," but as judged in depressed patients, its use produced more obvious improvement than interviews, ECT, or hospitalization alone. It showed the strongest predictable antidepressant action, and could be used on a continuous basis in minimal doses when required (rarely) as a maintenance therapy. Likewise, combined use of antidepressant and ataractic ("up and down") drugs is emphasized only because agitated depressives and disturbed acute schizophrenics require ataraxic-controlled activation to avoid the panic and assaultiveness produced with energizers alone(1, 3).

Numerous reviewers have demonstrated the errors in over-enthusiastic, under-con-

trolled clinical drug evaluations, some as succinctly expressed as: "Results always seem to be good with the 500 new pills left by the salesman"(7). Blind studies with placebo controls are widely used as the best method of reducing subjective evaluations by both patients and doctors. The present study utilized identical inactive placebos; in addition, the 2-year consecutive series of patients, with different drugs added in groups with long subsequent follow-ups, allowed each patient to act as his own control. Since there were regular rotations of what originally appeared to be equivalent drugs, the "therapeutic zeal" and personality of the physician were identical factors for all drugs, leaving only the differences between the various antidepressants—which were considerable—as the explanation for the differing results.

Patients were followed for at least 4 weeks after discontinuance of medication. These were all private patients, interviewed at least weekly, and often 3 times a week. A complete physical and laboratory examination preceded the therapy, with a routine urinalysis, Hb, WBC and alkaline phosphatase, the last 3 tests being repeated bi-weekly thereafter. The patients on ICZ were started with 10 mg. t.i.d. p.c. Divided p.c. dosage minimized any hypotension and tranquilizer "reinforcement." Dosage was usually decreased at a rate depending on improvement.

Dosage is as important as the type of drug being used. This is true of all potent compounds, and is well illustrated by serotonin, where small doses excite cortical synapses while larger doses inhibit them, thus reversing the increased electro-cortical potentials produced by the lower dose.

NEUROPHARMACOLOGIC MECHANISMS AND EFFECTS OF ISOCARBOXAZID INTERACTION WITH BARBITURATES AND NEUROLEPTICS

Amine oxidase inhibitors so obviously potentiate barbiturates that this property has been made the basis of the most common method of amine oxidase determinations in laboratory animals, namely, the extent of sleep prolongation following the administration of standard barbiturate dosages. This effect presumably occurs largely in the liver and results from blocking the

amine oxidase breakup of the barbiturates.

Since ICZ was the strongest antidepressant, its "potentiating" effect on other drugs would be presumed to be high in assisting (or interfering) with therapy, depending on what was desired. Although a small but definite amount of tranquilizer "reinforcement" is probably always present with ICZ, this has not been sufficiently great to necessitate neuroleptic dosage reduction. If both are used together, as is necessary in all agitated depressives and schizophrenics, the potentiation is present all the time, but does not produce a noticeable change from the tranquilizer dosage used in equivalent patients not on ICZ.

In addition to INZ's known mood-elevating effect, both tranquilization and a "neutral" response have frequently been reported from the use of INZ alone (8). The early rise in serotonin (5HT) levels and a later increase in norepinephrine (NE) have been observed (9), the 5HT increasing before any mood-elevation has become evident. The subsequent NE rise correlates fairly well with the appearance of clinical improvement in the depression. Many INZ patients have appeared calmer shortly after beginning the drug:¹³ their agitation was temporarily reduced from INZ alone, then reappeared and persisted until clinical depression improvement appeared. The "tranquil" effect, when present, occurred twice as fast as depressive improvement, and as will be described, can be deliberately used to improve phenothiazine control of agitated patients.

Tranquilization from INZ alone approximately correlates with a serotonin increase; mood elevation coincides with norepinephrine. Since the 5HT rise persists during the NE increase, it is reasonable to explain part of the obvious difference between amphetamine and INZ actions as a persistence of a mild tranquilization effect during the "stimulation" produced by INZ (10).

A temporal correlation of NE with mood elevation and 5HT with calming does not

necessarily imply a direct causation. The 5HT-NE and clinical changes can be "epiphenomena"—factors appearing to vary together, but both actually responding to the same basic cause, not yet elucidated, variations in it alone producing changes in both anxiety/depression response and 5HT/NE levels. ICZ shows this same "stimulation after tranquilization" effect as INZ, the sequence taking 3-5 days in contrast to the 10-20 days with INZ. The calming action of ICZ itself appears to be the biggest factor in the moderately increased sedative effect when tranquilizers accompany ICZ.

A great deal of concern has been evidenced in the literature about tranquilizer-sedative-alcohol dosage reduction in the presence of amine oxidase inhibitors. The above direct tranquilizer effect of ICZ appears to be the largest factor in this "potentiation." As has been mentioned, this effect is not great enough to require more than moderate reduction of tranquilizer dosages, and even failure to do this does not cause severe adverse effects.

ICZ's "double action" illustrates why it can both lift a depression and calm a moderately anxious person when used alone. The ICZ calming effect is not strong enough in a very agitated person, so it has to be increased by added tranquilizers. ICZ "over-stimulation" results only when the dose is "pushed" to gain the fastest possible improvement, or when it erroneously is not reduced as the patient is improving. A second purpose of simultaneous tranquilizers is to provide "insurance" control of "over-stimulation" if it accidentally occurs. This is unnecessary in the great majority of patients, since reasonably precise ICZ dosage control is entirely sufficient. ICZ, unlike ECT, stimulants, or therapeutic psychotomimetics (e.g., JB-329),¹⁴ can lift a person predictably above himself to carry him through crises or to help him face and get started in especially important situations when anticipation is more upsetting than realization; unlike stimulants, subsequent reduction of ICZ dosage does not produce a drug-rebound depression. Since it is better to have a patient more sedated than in a near-panic from "over-activation," the de-

¹³ Patients taking both phenothiazines and antidepressants often notice increased lethargy immediately after an increase in the latter alone; from this they naturally conclude that the amine oxidase inhibitor is the tranquilizing half in the combination, and then unfortunately later may decrease it if they feel too tired.

¹⁴ Ditrin, Lakeside Laboratories, Inc., Milwaukee, Wisconsin.

liberate intent in "balanced" therapy initially always is to keep the patient on the "calm" side of the tension-depression continuum.

If a patient is extremely disturbed and not controlled with high doses of multiple phenothiazines, occasionally the addition of even 10 mg. of ICZ daily will provide improved control. The "potentiation" of a large phenothiazine dose by a minimal amount of ICZ is clinically greater than the expected activational effect. A possible explanation for this paradoxical effect is through Hess' thyrotropic-ergotropic control mechanism(11, 12) as adapted by Brödie(9). A high dose of chlorpromazine produces a relatively complete ergotropic (norepinephrine) blockade, but has no effect on the sedative trophotropic (serotonin) mechanism. ICZ would usually increase both NE and 5HT levels, the elevating action of NE being the more obvious one clinically. Since chlorpromazine blocks any NE stimulation, ICZ then produces only an increased serotonin level and a consequent reserpine-type tranquilization through trophotropic stimulation. This paradoxical or "reverse" tranquilizer effect of ICZ is useful in this special situation but is obviously not applicable with low tranquilizer doses since enough phenothiazine must be present for a complete norepinephrine blockade. A controlled motivational system is basic in the human, whether anxious, eutonic or apathetic, but shows marked dysfunction in depressive syndromes(10). Since activators and tranquilizers affect this system in opposite directions, it would seem that these drugs would cancel out, but in clinical practice effective doses of each exerts the usual effect in the presence of the other.

There was no evident change in seizure threshold in patients given ECT while on INZ, nor is there with ICZ. Although theoretically alcohol would be considerably potentiated by ICZ, thus decreasing a patient's capacity for drink, in practice the change in tolerance is minor and less than the chlorpromazine potentiation of alcohol. In fact, a review of 5 patients who drank while taking ICZ (the alcohol was their idea) showed they could drink more during the evening and retain better control. ICZ

is also by far the best treatment for a "hangover," but since it must be started the week before, this property of the drug is useless therapeutically.

ICZ's improvement of "hangovers" has to be thought of when prescribing it for a patient with a history of alcoholism. Since drinking, with its escape from responsibility, has long been psychoanalytically recognized as a depressive equivalent, this problem often arises(13). If the depression is acute and definite, INZ will usually bring improvement before the facilitation of alcohol is noticed. If it is chronic or the diagnosis tenuous, the patient may very well use the drug only to help maintain his drinking by reducing "hangovers," thus increasing the ease of escape.

SCHIZOPHRENIC REACTIONS

ICZ with a supporting neuroleptic provides good symptomatic improvement in acute illnesses of depression and withdrawal, but in addition to therapy it simultaneously and accurately delineates diagnosis, prognosis, ego strength and adaptability through comparisons of clinical changes with dosage. Because of their ego fragility, acute schizophrenics provide good examples of how ICZ response can measure personality resiliency. However, and more importantly, they are the patients whose ego tolerances must be known in advance by the physician since an antidepressant overdose can release confused and erratic behavior in all acute schizophrenics except the severe paranoids. The latter's illness has abruptly reached the epitome of rigidity and these patients have already erected the supreme and final defense to avoid the necessity of fighting off (adapting to) successive stresses through developing a stronger defense for each one.

The "supreme defense" is universal and all-inclusive: the patient never is bothered by further conflict or ambivalence. The total displacement of retaliating super-ego onto the outside world permits him to live in and near conflict but to be affectively (emotionally) detached. His "reasoning" is rational (if one accepts the premises with which he starts) and is self-perpetuating since each apparent social deprivation only re-enforces it still further.

Once the "supreme defense" stage has been reached, the patient has become self-ambulant (but for very "sick" reasons). ICZ cannot reverse his paranoid trend (there is no therapy that is very effective in doing this), and could only speed up his behavior with unpredictable results. Neuroleptics slow such a patient but do not change the mechanism either. However, for all stages of acute schizophrenic illnesses including early and acute paranoid ones, ICZ with a neuroleptic produces good results without the memory loss and relapses of ECT.

A patient with acute catatonic schizophrenia of 3 weeks' duration has almost as good a prognosis as one with an acute depression of the same duration. However, the ego boundaries of the depressive are sufficiently stronger that ICZ can often be used alone, whereas the schizophrenic fragility requires cautious ataraxic-controlled activation. With such control an equal amount of ambulating therapy can be given the schizophrenic.

Table 2 shows the somewhat less effective results of the drugs in acute schizophrenics, although here also a combination of ICZ and INZ was the most effective, and ICZ was the most effective of any drug used alone.

ISOCARBOXAZID VERSUS ELECTROTHERAPY

For the sanitarium psychiatrist who has had to suffer through comments that he is "shockhappy" and that all his patients get

the same treatment, the antidepressants have been a great help. The marked decrease in necessary hospitalization and ECT produces a drastic economic reduction for both the sanitarium and its psychiatrist. It is to the credit of the profession that antidepressant usage has spread so rapidly.

Eighty-six percent of the ICZ patients in this series could maintain their improvement with careful reduction of dosage, while none of the patients showed even a mild relapse with a decline from the dosage level which produced their original improvement. This is in tremendous contrast to the 30% of patients on electrotherapy who relapse while treatment is still continuing. From over 200 comparisons, it appears that ICZ can totally replace "raw AC shock" treatments since the confusion produced by the latter limits the rate at which they can be given.

Lehman(14) feels that ECT is the treatment of choice for the suicidal depressions since he thinks it is faster and more predictable than drugs. This is difficult to understand since ICZ often produces improvement in 3 days, is *more predictable* and controllable, and shows no third-week or post-treatment relapses. The freedom from relapses is partially due to the fact that the patient can temporarily remain on a maintenance dose at home. The rapidity of effect results from ICZ's ability to cross the blood-brain barrier; the benzene ring is apparently the factor responsible for this permeability. The addition of INZ to ICZ accelerates

TABLE 2
ACUTE SCHIZOPHRENICS

Agent	No. of Patients	Marked	Per cent Rehabilitated Moderate	Total
Isocarboxazid	51	53	27	80
Phenelzine	46	48	24	72
Iproniazid	43	40	26	66

Isocarboxazid & Iproniazid	21	57	29	86
Isocarboxazid placebos	16	13	25	38
ECT (Standard AG)	168	84	5	89

recovery to where it equals the speed of any type of ECT but without memory loss.

Although results in the approximately 1,800 patient illnesses show ICZ to be the strongest antidepressant, equaling or exceeding "raw AC" ECT, the overall figures are not quite as dramatic as case histories.

A case in point is that of a 67-year-old widow with a 20-year history of moderately severe depressions, the total duration of which filled half of the 20 years. The patient had had every conceivable form of treatment throughout that period, but the results were so bad that her family noticed that improvement occurred just as rapidly without any care—within 3 to 6 months—as with it. Three years ago, 3 months of improvement followed 3 months of hospitalization and 37 ECT's. One year ago she improved within 2 weeks on INZ, but slowly relapsed following disabling back injury. The patient improved possibly 30% in 3 weeks on phenylethylhydrazine,¹⁵ but subsequent dosage increases did not bring about greater improvement. On 75 mg. of INZ daily, she again improved slightly. With ICZ, the patient exceeded even her previous improvement with INZ to the point where the past 7 months have been her most active period in the last 5 years.

LACK OF TOXICITY AND SIDE EFFECTS

As stated above, alkaline-phosphatase determinations were done for every patient every 2 weeks. In all but 3, these ranged between 1.8 and 3.7. Two patients showed elevations of 4.3; the drug was continued in both since they were entirely asymptomatic. Within 2 weeks the tests returned to normal without incident.

The third patient developed a minimal infectious-type jaundice 4 weeks after starting chlorpromazine 300 mg. a day, and 5 days after being transferred from INZ and phenylethylhydrazine to ICZ 30 mg. daily, he was continued on the latter at his and his family's insistence because of the extreme severity of the depression which had just begun to show improvement. He developed what appeared to be minimal scleral icterus on 25 mg. chlorpromazine t.i.d. for 3 weeks, and 30 mg. of ICZ for 7 days. The patient's symptoms were minimal in comparison with those of the 6 chlorpromazine jaundices the author has

treated, while the risk of suicide or elopement had been extreme for several months. He showed minimal scleral icterus and gray stools for 6 days, with an abrupt total disappearance of both on the seventh day.

This case was the only instance of jaundice in 206 patients given chlorpromazine delayed-action capsules; in the previous 2 years, 6 cases occurred in 288 patients receiving chlorpromazine tablets.

The occurrence of this mild jaundice 4 weeks after initiation of chlorpromazine, and its improvement while ICZ was continued, seemed to justify the diagnosis of an abortive infectious or chlorpromazine hepatitis. Although there are certainly other explanations for what occurred, and one case does not warrant general conclusions, the fact that a definite acute jaundice improved while the patient was taking 20 mg. of ICZ daily is reassuring as to the drug's effect on existing disturbed liver function. In none of the 195 patients was the drug ever discontinued because of side effects.

Many physicians may not share the author's enthusiasm for combined ataractic-antidepressant therapy. However, in considering the compatibilities and possible "synergistic toxicities" of a new drug like ICZ it is informative and reassuring that in 195 patients it was without serious side effects, even though throughout it was used with at least one phenothiazine, and occasionally with another antidepressant. Drugs with which ICZ was effectively used include chlorpromazine, promazine,¹⁶ prochlorperazine, perphenazine,¹⁷ mepazine, trifluoperazine,¹⁸ triflupromazine,¹⁹ iproniazid, phenelzine, phenylcyclopropylamine, imipramine, amphetamine, methamphetamine, mephentermine,²⁰ methylphenidate.²¹

Mild hypotension seemed somewhat less of a problem than it had been with phenylethylhydrazine, although it had not been frequent or severe with the latter.

CONCLUSIONS

Isocarboxazid, an iproniazid analog, showed better results in the treatment of 195 patients with depressive and acute schizophrenic reactions than were seen in varying numbers of patients on 7 other antidepressants, including 223 treated with iproniazid. With a median improvement time of 8 days, isocarboxazid alone equals or exceeds ECT in speed and effectiveness, and shows no major side effects.

Isocarboxazid appears to have the strongest "activation" effect of any amine oxidase inhibitor, is easily managed in maintenance usage, and can be combined with other antidepressants or tranquilizers, at least one of the latter having been used with it in every one of the 195 patients in this series. It is quite effective in both acute schizophrenic and depressed patients, and the fact that these diagnoses constitute 83% of private psychiatric hospital admissions indicates the potential wide range of application of isocarboxazid.

The mood-elevating effect of isocarboxazid correlates with the rise of norepinephrine, but not with the earlier serotonin increase. The frequently seen early sedative effect of isocarboxazid, however, does accompany the rise in serotonin. This "double-action" of isocarboxazid is one of the basic reasons for the sharp difference in its clinical effects from those of amphetamine.

Pharmacologically, "balanced therapy" is simply the outside reinforcement of the isocarboxazid tranquilization in agitated and disturbed patients. Although a good "balance" does not produce hyperactivation, under conditions of unusual stress the patient can be deliberately carried "higher." In the special case of extremely disturbed psychotics only partially controllable with high phenothiazine dosages, isocarboxazid can be used to provide a reinforcing reserpine-type tranquilization.

Concern about possible hepatotoxicity seems unwarranted, not only because there were no significant liver function changes during this study, but because a suicidal

risk with a mild chlorpromazine or endemic hepatitis showed clinical improvement and resolution of his jaundice while on isocarboxazid. The drug produces no obvious change in the ECT threshold and shows little clinical potentiation of alcohol but minimizes the "morning after." It "potentiates" phenothiazines sufficiently to improve the "tranquilization" of extremely disturbed patients.

CRIMINAL GENESIS AND THE DEGREES OF RESPONSIBILITY IN EPILEPSIES¹

RALPH S. BANAY, M.D.²

My interest was awakened in violence associated with automatism, and came close to ending abruptly at the very moment it was aroused, by a vivid personal experience in my office. I was alone with a new patient who complained of convulsive attacks with loss of consciousness, occurring every month or two. This had gone on from early childhood and no medication so far had reduced the frequency of the attacks. He was a baggage clerk in a railroad station, young and frail-looking, with a timid personality.

I was just finishing with his history and examination and was writing a prescription for an anticonvulsant drug when I suddenly became aware that he had risen from his chair in a rigid, mechanical manner and was approaching me with out-stretched hands. With an iron grip he attempted to choke me. He had a fixed, distorted facial expression and a vacuous look in his eyes. It required a rather desperate struggle to break his hold on my neck. In a few seconds he fell to the floor in a grand mal attack, with fixed pupils and foaming mouth. When the tonic and clonic states passed, he gradually regained consciousness, looking around in a daze. Later, when he was informed of what had taken place, he was completely amnesic. I learned later from his family that at times, in the incipient phase of an approaching attack, he had shown unprovoked aggressive behavior.

After this unforgettable experience, and repeated observation of cases in which the outcome was less fortunate, it has not been difficult for me to understand how many otherwise inexplicable crimes of violence can be explained as automatism associated with what we generically call epilepsy. Epilepsy is so variable in its manifestations and may occur in forms so obscure or evanescent that a sufferer of this syndrome can carry out a furious attack without conscious intention and without subsequent recollec-

tion of the event. It would seem that in criminal trials, both medicine and jurisprudence have given insufficient attention to this circumstance and that appraisal of the pathological phenomena involved, and vigilance for their detection, could well be stimulated.

Epilepsy, of course, is one of the persistent enigmas of medicine. Its wide-ranging symptomatology, which is a manifestation rather than an entity of disease, continues to engage the labors of investigation. In spite of advancing knowledge of the epileptic phenomena and brain pathology, as well as psychochemical action in the brain, the accumulated findings tend to consist largely of description rather than definition. After some 24 centuries of observation and study of what the ancients called "the sacred disease" and Hippocrates recorded as "falling sickness," conclusive elucidation of this pathology lingers on as an item on the agenda of biological science for future disposal.

No one knows how many epileptics there are. The number of known convulsive cases in the United States is said to be close to 1,500,000 and the number of chronic cases requiring institutional care 50,000. Some investigators believe that one person in every 200 is a potential epileptic. Nearly every practitioner is aware of sizable numbers of persons who are afflicted in some degree with epileptic symptoms but who neglect or refuse to obtain treatment. How many others have a latent or dormant tendency to some of the many forms of epilepsy can only be imagined.

In over-all effect, the management of the affliction is a matter of palliation and control rather than progressive treatment. Great numbers of relatively moderate sufferers are enabled, by medication and counsel, to engage in normal pursuits. They remain in employment or other forms of endeavor without major difficulty and lead virtually normal lives. They are licensed to drive automobiles under proper certification of med-

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² 927 Fifth Ave., New York 21, N. Y.

ical control. *The problem and public dilemma concerns those others who do not even know themselves that they are potential epileptics or who, aware of the difficulty, choose to do nothing about it.*

The oft-quoted dictum of Oliver Wendell Holmes remains a challenge to medical ingenuity. The physician and poet said just a hundred years ago: "If I wished to show a student the difficulty of getting at the truth from medical experience, I would give him the history of epilepsy to read." He was aware that epileptic automatisms were clearly recognized by 16th and 17th-century physicians. In our day, as in his, the traditional evasive tenet that the affliction is a divine visitation beyond human remedy no longer impedes scientific endeavor. Medical and biological investigators have made important strides toward understanding and countering the liability to convulsive seizures, but that there is still a long way to go is evidenced by our frequent puzzlement over the sudden and unforeseen eruption of violent automatism.

In reading time-steeped medical literature, one is often prompted to ask whether we have given sufficient acknowledgement and attention to those pioneers who proclaimed vivid insights on many of the problems that still perplex us. For example, Isaac Ray wrote in 1860:

The dementia which is the form of mental derangement to which epileptics are most liable after the fit is characterized by intellectual stupor and moral depression, in which, however, they have sufficient energy, under some circumstances, to commit acts of violence, of which they retain only an imperfect recollection after they recover.

The insufficiently appreciated English physician Henry Maudsley, writing more than 80 years ago, made this observation:

Certainly the most desperate instances of homicidal impulse are met with in connection with epilepsy. The attack of homicidal mania may take the place of the ordinary epileptic convulsions, being truly a masked epilepsy. The diseased action has been transferred from one nervous center to another, and instead of a convulsion of muscles the patient is seized with a convulsion of ideas.

Maudsley also cautioned:

It is important to bear in mind that the existence of epilepsy may be overlooked for some time in a person even by medical men, and this is perhaps more likely to be the case when there is a mental alienation which absorbs the attention. Attacks of epileptic vertigo are sometimes so slight that they are thought to be merely transient attacks of giddiness or faintness; and it is notorious that patients will often seek advice on account of some ailment which they attribute to the stomach or the liver, the real nature of their malady being elicited only by accident.

Maudsley commented that such cases often "occupy the borderland between crime and insanity." He spoke also of what he called the low physical and mental characteristics of criminals.

Lombroso emphasized the relationship between epilepsy and the criminal nature. However, in his attempt to attribute abnormal skull formation as etiology of both epilepsy and criminality, he blurred the true significance of his researches.

After this long history of what might almost be called intermittent bursts of interest in the problem of automatism, should we not feel somewhat embarrassed by the fact that our knowledge of the pathology even today remains nebulous and amorphous, and even more so by the fact that so many persons susceptible to the disorder remain unrecognized or untreated until a grievous outburst has advertised their affliction?

Wilder Penfield has observed that:

the automatic individual has lost the means of comparing the present situation with previously established concepts. In this confusion, this failure of understanding, his loss of ability to record his present perceptions is complete. This seems to be the essential defect. . . . Automatism is the temporary ictal, or postictal, state of a patient, who has not lost motor control but lost, to some degree, his understanding and has complete loss of capacity to make durable memory records.

Sakel, out of his experience with insulin shock therapy in the treatment of schizophrenia, made many penetrating observations on the convulsive mechanism. He con-

ceived of the convulsion as a defense process seated in the vegetative nervous system, a crisis invoked in an automatic way to cope with any threat that may occur to the body. He defined it as a normal response of the nerve tissue to excessive irritation, acting to restore a disturbed equilibrium to normal on the principle of homeostasis. He found, incidentally, that emotional factors play a part in aggravating the number and seriousness of the seizures.

Epilepsy has been variously attributed to congenital defects, prenatal injury, trauma, febrile thrombosis, neoplasms, degeneration and arteriosclerosis. The seizure has been described as a literal physiological brainstorm with biochemical, endocrinological and genetic aspects, involving the mechanics of psychological processes. The fact that only some patients with head or brain injury develop convulsions has supported the assumption of an hereditary predisposition.

Practitioners and clinicians have long recognized a fairly standard trend of personality patterns in epileptics in general. These are characterized by emotional immaturity, extreme conceit, hypersensitivity and restricted interests. MacCurdy has described the typical epileptic as being considerate without being kind, religious without zeal and inclined to work for praise but not for love. It is a pattern that, together with emotional instability, volatility and a likelihood of irresponsibility in crisis, could be expected to react violently in the event of stress.

The existence of a considerable number of persons who are definitely epileptic but evade treatment is illustrated by the case of a young man who acknowledged frequent blackouts. The scion of a well-to-do family, he was well supplied with financial means to indulge his oscillating moods. While driving his car he would periodically pull up at the side of the road when he felt one of his minor seizures coming on, and would proceed when it had passed. He wrecked a number of expensive cars in accidents attributable to this instability. Referred for therapy after one of his escapades, he beligerently refused to cooperate in treatment, considering this acknowledgement of his affliction an affront to his ego. Though warned

of the seriousness of his condition and assured that it could be controlled, he flouted his family's efforts to help him. Eventually, he became involved in a financial speculation explainable only by his irresponsible personality pattern and suffered legal consequences for it.

A case of what may be termed preventable murder involved another young man whose plainly pathological condition was aggravated by excessive drinking. He had been discharged from the army as epileptic and this finding had been confirmed in several psychiatric clinics. One evening he sat in a bar drinking and there lapsed into an amnesic interval. When his awareness returned he found himself in his car, parked in a lovers' lane. Beside him was the body of a girl with whom he had been friendly and beside her a blood-stained wrench with which she had been battered to death. In spite of the recorded evidence of his epileptic condition and the obvious deduction that alcohol had provoked his furor state, he was convicted of first-degree murder because no testimony could be adduced that he had been in a state of seizure when the murder was committed.

In another case a boy of 13, while playing with a girl of 7, tried to experiment sexually with her. When she screamed he beat her on the head with a rock, killing her. His family assented to a plea of guilty to second-degree murder and, in spite of his age and medical testimony that he was indisputably epileptic, he was sentenced to prison for 30 years to life. His history showed chronic enuresis and episodes of morbid preoccupation with killing animals and insects, as well as several instances of fugues when he was found as far distant as Florida and California without recollection of his wanderings. In prison he suffered two to three grand mal attacks weekly. It is now more than 10 years since he was sentenced and at last report the prison physician still found it necessary to keep him under anti-convulsant medication.

My experience with organically determined violence in young people was highlighted in the case of a boy of 14 who murdered with exceptional brutality. precociously husky and muscular, he was visiting an aunt, 23 years old, the mother of two

children and pregnant, to watch television. When the young woman complained of feeling unwell and asked the boy to leave, he was overcome by a "sudden urge" as he rose to go. He struck her in the face and when she fell kicked her about the face and head. He struck her again with a soda bottle, brought a metal spray gun from the next room and struck her with that. He then beat her with a lamp, obtained a large knife from the kitchen and stabbed her in the neck. Still in furor, he wound a lamp cord around her neck and was dragging her to the kitchen, intent on stringing her body on a water pipe, when a knock on the door alarmed him and he fled through a window. This boy had a history of two serious head injuries and of blackouts attributable to them. His only previous offense had been car thefts, carried out in frivolous disregard of the likelihood of detection. He was clinically found to be epileptic as a consequence of brain injury. On at least one occasion while he was in a custodial institution he had an unprovoked outburst of characteristic furor in which he struck a wall violently with his fists.

Another case involved a young man accused of killing his mother. There had been an argument between them about the painting of a room. The son left the house and when he returned his mother was on a step-ladder proceeding with the painting job. The argument was resumed and the young man claimed to have no clear recollection of what followed. But it appeared that the mother fell or was pushed from the ladder and was killed when her head struck a marble abutment. There were significant sequels. I was asked to examine the young man and to elude his recollection of the obscure episode. I injected a few grains of sodium amytal. As soon as the drug took effect he became violent and assaultive and was prevented from attacking me only by the presence of others who were able to restrain him. On another occasion while in custody he vented a sudden unprovoked burst of rage by striking a wall with such force that it left a hole in the plaster. Later

he was committed to a state hospital and in a similar outburst there he struck a beam so violently that the lumber was displaced. Thus we had several demonstrations of the spontaneity with which such a person, subject to sudden outbursts, can erupt in violently aggressive episodes without warning or observable provocation.

Reflecting upon such cases as these, the frequency with which they occur and the varying medico-legal attitudes assumed in assessing them, one feels that it is time that we agree upon ways of evaluating them from the standpoint of prevention as well as juridical disposition. We have had enough experience in this field to determine the necessary precautions and procedures. It is not a problem for psychiatry alone; general practitioners and pediatricians need to be kept alert to the dangers that can accrue from a great variety of pathogenesis: prenatal trauma, feverish childhood diseases, injuries, encephalitis and all the other possibilities of brain deficiency or damage which might lead to convulsive syndrome and severe antisocial behavior. Where abnormal symptoms occur in behavior or in pathology, we would do well to exhaust every resource of diagnosis and therapy to forestall the serious consequences of liability to convulsive disorder. EEG examination should be routine where any such tendency is indicated, and even negative findings should not be regarded as conclusive.

The medico-legal problem presented in epilepsy is one that concerns primarily the patient susceptibility to automatism in seizure, or the equivalent of seizure. Even when it can be shown that the perpetrator of a violent crime was acting without conscious volition, a court is unlikely to agree that the person is not legally responsible. Under the McNaghten Rule such defendants are not definably insane. It is a dilemma in which all of medical science must feel constrained to offer to the legal authorities every possible lead in the evolution of a workable, equitable formula.

REINTEGRATION OF PSYCHOANALYSIS INTO TEACHING¹

GEORGE C. HAM, M.D.²

Psychoanalysis as a theory, as a method of investigation, and as a technique of treatment has in a few short years been strikingly, if unevenly, integrated into medical education, research and practice. This represents a radical change from two decades ago. During these 20 years the chairmanship of several departments of psychiatry have been awarded to men who were fully trained psychoanalysts; many others to men well acquainted with the principles and concepts of psychoanalysis. The majority of other medical school departments of psychiatry have included as fundamental principles many of the discoveries and basic concepts of psychoanalysis. Curriculum time for the undergraduate medical student has been dramatically increased to admit the introduction of these principles as basic factors in human development and human behavior. Knowledge of the development, mechanisms and disturbances of the psyche have come to be considered by many medical educators as essential to medical diagnosis and treatment as the same basic understandings of the soma have been for years.

Graduate training of specialists in psychiatry has grown markedly in numbers, quality of training programs, and in support by state and federal agencies. Along with the support of specialty training in psychiatry has been the parallel strengthening of training in psychiatric nursing, clinical psychology, psychiatric social work, and more recently, of social scientists in the field of mental health. These disciplines together have brought a new excitement in the revealed, hopeful results from understanding inter and intra personal processes. The development of remedial treatment that is stemming from these new understandings has led to major growth in both basic and applied research in the field of mental health by many medical disciplines. It is

clearly evident that these changes, both in the undergraduate medical school curricula and in the growth of graduate training programs, has resulted from the new beacon of hope that has derived from the application of extended understanding of human health and illness in breadth and depth, and from the real and demonstrable improvement in techniques of treatment and of prognosis. New areas of investigative opportunity have developed as a consequence.

Many of these changes can be attributed to the introduction of the basic concepts and techniques of psychoanalysis. This is true, even if the word psychoanalysis, the source of many of the principles, is obscured under the rubric dynamic psychiatry.

Psychoanalysis then, as compared with 20 years ago, is in a highly "prosperous" position in academic medicine and in residency training generally. The late Allen Gregg, speaking in 1952, reported that a former professor of his, Thomas Nixon Carver, a sociologist, in the year 1910, described the accomplishments of man in terms of adversity. Dr. Carver outlined the major advances that had been made in controlling two major adversities—epidemics and famine. At this point, Professor Carver took off his glasses for a moment, looked out over the class, and added this prescient observation:

"I suspect that some of you young gentlemen may witness the beginnings of a new kind of struggle for survival. The question for you may not be 'Who will survive adversity?' but 'Who will survive prosperity?' And gentlemen, to guide it in the struggle to survive prosperity, the human race has yet but little experience, common knowledge, or tradition."

Dr. Gregg then went on to state,

that those who are making the history of psychoanalysis—and I here refer to it in terms of its relationship to teaching in medical schools or in residency training programs—could sensibly reflect upon the problems of surviving prosperity. It is all but needless to say that I do not have in mind the charges or the income

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Chairman, Department of Psychiatry, UNC School of Medicine, Chapel Hill, N. C.

of psychoanalysts when I speak of prosperity. The issue transcends that petty consideration. A greater task confronts you. Psychoanalysis has survived the adversities of opposition, obloquy, disdain, disgust, hatred, and fear. It has been evaded by academic psychiatrists, condemned by universities, condemned by churches, ignored by hospitals. Ridicule, persecution and ostracism, if such winnowing may appear to deserve the name of adversity, psychoanalysis has survived. But now it faces the task of surviving prosperity—prosperity in the form of admission to academic status, of being tolerated, of being accepted, of having attention and deference, and most important of all, of being in demand. This surviving prosperity being a relatively new task, you will have but little experience, tradition or knowledge to steer by.

The fact is that in relationship to academic teaching and specialty training, psychoanalysis has many of the problems of the nouveau riche. We must face these new responsibilities, the new potentialities for contribution, the inherent criticism, misunderstanding, and misinterpretations that are part and parcel of any change, and with patience and objectivity, maximize the opportunities that are, and will become, available for continuing growth and synthesis with medicine in general and health and illness in a broad perspective, in particular.

The title of this symposium is "Reintegration of Psychoanalysis." I am addressing myself to "Reintegration into Teaching." If we use the psychoanalytic model, it is imperative to understand the present, which I have just outlined, in terms of the genetic and determinative past, in order to understand the mechanisms, work through the defenses, and maximize the opportunities for ego growth for the future.

Out of the genius of Freud, a physician, came the discovery of a truth about man that was so frightening, except to a few, that he was cast out of academic medicine into the relative obscurity of defending and developing his discoveries with the aid of a small body of courageous exiles. His discovery, demonstrating that man is not complete master of himself, like the findings of Copernicus, that the earth was not the center of the universe, was not accepted into general knowledge for a number of years. The requirement that Freud and his fol-

lowers be self-supporting as practicing physicians, as contrasted to what might have taken place had they been in academic posts, influenced the development of psychoanalysis as a method of treatment, and for a number of years directed emphasis on the training of practitioners. The development of the Berlin Institute and the subsequent development of excellent psychoanalytic institutes throughout the country is evidence of the courage of the people who developed and maintained them. The tremendous post-war demand for training by psychiatrists in the psychoanalytic institutes was and is evidence of the demonstrated value of its concepts and principles. The history and the function of these institutes is well known. Although in the United States psychoanalytic institutes were dedicated almost entirely to the training of psychiatric physicians for psychoanalytic practice, most remained outside the general body of medicine, as represented by medical schools and residency training programs. The staffs of the institutes were largely private practitioners, as was Freud, and part-time teachers. Gradually, however, some institutes became involved in research related to general medical problems in the area of "psychosomatic medicine" and in relation to pediatrics in the area of child psychiatry and child analysis, as well as with psychologists, social scientists, social workers, and others. Although these investigative problems impinged with increasing emphasis on areas within general medicine, it was only in recent years that some members of the faculties of psychoanalytic institutes began, on part-time basis, to participate in teaching within medical schools and in residency training. At the beginning of this discussion, I indicated the changes that have occurred in the most recent period toward acceleration of academic acceptance of psychoanalysts and of psychoanalytic concepts and theory. In this sense, Freud has returned to academic medicine.

Although I am sure Freud would have rejoiced at this new development, he would have realized immediately that the substantive content, pedagogical techniques as well as the goals of psychoanalytic institutes could not be transferred in unaltered form and satisfy the new needs and problems of

medical students and residents. He would have realized that just as a few banded together with him to form the nucleus from which came the tremendous development of psychoanalytic institutes and psychoanalytic training as it is today, there would be the same need for mutual support of the early adventurers into this new area of responsibility and application. Indeed, 8 years ago, a group of us who as psychoanalysts had accepted the chairmanship of departments of psychiatry in medical schools, did develop a mutually supporting organization. Interestingly enough, these 7 men facetiously named their group the Beachhead Club appropriate for an Army landing on a hostile shore. It is significant to note that after several years of mutually supportive meetings, the name was changed, indicating increased security, to one more appropriate for pioneers invading and traversing a new land: the Stagecoach Club. This name is still active and pertinent.

What are the problems, challenges and opportunities relating to the introduction of psychoanalysis into medical education and into residency training programs?

At the outset, let us consider certain general factors regarding the social and conceptual realities of medicine into which psychoanalysts seek reintegration. On the one hand, medical progress and academic medicine for the past 60 years have been largely influenced by the development of the physical and chemical sciences. These developments have permitted the amazing particularization and atomization of the structure of the body and of its component parts. These sciences have grown with amazing lushness as branches, twigs, and leaves of a luxuriant tree from a sturdy trunk which is in the tradition of the structural concept of the pathologist, Virchow. The tremendous success in the eradication of many illnesses of this relatively simple concept of structural change as the cause of symptoms, persists as a mighty deterrent to the transactional or multifactorial concept of human adaptation and illness that has derived from psychoanalytic thinking. It persists in the open expression of expectation that the so called mental illnesses will be "cured" by the simple expedient of discovering the disturbed enzyme system and the administration of

the appropriate chemical to alter this state. The traditional medical curriculum under this influence has been divided into two years which are dedicated to the "basic sciences" and two years to the clinical sciences. The basic science years require the detailed study of parts and sections of the body in terms of their normal or altered anatomy, physiology, biochemistry, *etc.* This attitude of understanding illness as resulting from disturbed anatomy or function of organs or organ systems is carried over into the clinical years, where diagnosis and treatment tend to be focused upon searching for evidence of disordered organ function in the physiological or biochemical sense by highly developed laboratory procedures and the administration of appropriate substances or regimes directed at the disturbed organ system.

A change in values is well under way. However, it must be remembered that new concepts and attitudes, many of which have been derived from psychoanalysis, which are broadening our concept of health and illness were not part of the formative student years of the majority of the leading physicians in academic medicine in all other branches of clinical sciences. This is even more true in the basic sciences of medicine where many of those who set the intellectual model are Ph.D.s highly skilled in their particular field, to whom the concept of developmental adaptive holism is in direct contradiction to the concept of finer particularization of structure. Secondly, these scientists, including the clinical specialists, rely on quantitative measurement of biochemical or biophysical processes and have developed ingenious machines to make this possible. In contrast, the proponent of the scientific application of psychoanalytic understanding to human health and illness must rely largely on prediction, a measuring device open to criticism because of the subjective values inherent in the method in the measurer and because of the time required in the process of measurement of predictability.

In view of this sociological dissonance between the structural and dynamic adaptive concepts, it may be useful to pause a moment to examine some of the forces that led to the exciting but uneasy marriage that has occurred. It is largely since 1945, that re-

turning veterans, impressed with the success of psychoanalytic principles in treating war neuroses, created a demand in medical teaching for the inclusion of more than the unsatisfying descriptive and organic psychiatry of the past. This movement was aided by the appalling discovery of the high percentage of incapacitating psychoneuroses, psychosomatic disturbances, psychoses, and behavior problems in the induction stations throughout America incident to mobilizing for the great conflict. These pressures resulted in the rapid acceleration of the introduction of psychoanalysts into medical schools as chairmen of departments or as members of faculties and the introduction of derived concepts of psychodynamics into medical education. The consequence was the introduction of increased time to departments of psychiatry including the opportunity to introduce in the pre-clinical or basic science years concepts which were direct progeny of psychoanalytic thinking. These were introduced under various names such as human development, psychodynamics and the life cycle, human ecology, introduction to medical psychology, introduction to psychiatry, *etc.* In many schools, such courses are conducted in collaboration with other clinical departments and some basic science departments; in others, by departments of psychiatry alone. Many of these concepts were strange and disturbing both to students and to existing faculty of other departments. These new courses demanded inclusion and examination of many more factors than had previously been required in the armamentarium of a competent physician. The relative absence of the type of experimental evidence and quantitative data used in other sciences to validate theories and hypotheses required students and non-analytic faculty to accept "on faith" many of the principles taught in these new courses, including the demand that a present illness be looked on as a maladaptive state which could only be understood in terms of the entire history of the particular human being involved; that what appeared to be illness in the usual sense could be viewed as the only adaptive opportunity available to this person at this time commensurate with life and in this sense represents a successful adaptation; still further

emphasis was placed on the present being a continuation of the past; the demand for knowledge of the day-by-day development of each individual from the genes through the gestational period and the entire life cycle; the fact of instinctual drives; of unconscious determinism; of the reality of psychosomatic and somatopsychic relationships; of the fact of transference and countertransference as manifested in the doctor-patient and other relationships; of the non-specific effect of drugs; of the production of structural change secondary to intrapsychic conflict as the result of environmental maladaptive states—a complete reversal of the Virchow position; the realization that the so-called mental illnesses merely represent an exaggeration of everyday mechanisms of human behavior and adaptation; the facts of determinism and of teleology and of the dramatic results of words and human attitudes in the form of psychotherapy, upon psychological and biological states and on integrated behavior; of the realities of sociological and anthropological influences as productions of man, and therefore amenable to man's correction and alteration—all of these and more required a perspective and a synthesis into the existing body of medical knowledge that both excited and threatened faculty and students alike. The natural result of this state of affairs in human beings is insecurity. Insecurity can stimulate the development of emotionally colored defensive positions. A tendency develops within the atomistic sciences to become more atomistic and to demand "scientific" evidence from the adaptive behavioral group using their familiar methods of quantitative measurement. Likewise, the prosperous newcomer, with his shiny new concepts, tends defensively to strengthen his different dialect, and indeed, a different dialectic. A tendency develops for the two groups to place themselves on opposite sides of that blinding beacon, truth. One can at times come to despair of mutual recognition by observers in both camps. They seem unable to see beyond the great light and into the faces of the other observers who see the light too. A gracelessness develops in each discipline in the study of man. Each becomes too insecure to give, even, to give thanks.

In my opinion, this represents the greatest hazard to the reintegration of psychoanalytic principles into the body of medicine. It requires the application derived from our psychoanalytic knowledge of the maximum patience, of maturity, of working through. It requires the grace of openness, the grace of acceptance of real criticism, honest attempts to bridge the gap of scientific confusion and distrust, and the alleviation of the defensive tower of Babel.

These goals of a mutually acceptable synthesis, although fraught with many hurdles, can be obtained. A synthesis which offers a frame of reference and an opportunity for collaborative teaching and research for all medical disciplines has been beautifully developed and described by George L. Engel, in the book, *Mid Century Psychiatry*.³ Dr. Engel's paper entitled, "Homeostasis, Behavioral Adjustment and The Concept of Health and Disease," clearly outlines 4 components which contribute to the clinical picture of disease, which I prefer to spell dys-ease, painful-ease. These 4 components include factors derived from the sciences of phylogenesis, biological adaptation and instinctual drives. They are :

1. The attempts at satisfaction of instinctual needs which have been interfered with.
2. The inner perception of a disturbed equilibrium or an unsatisfied need involving the concept of a danger signal.
3. The various adaptive devices old and new, chemical, physiological, psychological and social, which come into play to cope with the stresses, primary and secondary, to restore equilibrium and to assure satisfaction of instinctual needs.
4. The actual structural or functional damage which may result from the stress itself and from the attempts at adaptation which are inappropriate or unsuccessful.

With this background, allowing a unitary concept of health and disease, the task of medical science becomes clarified. All physicians, including psychiatrists and psychoanalysts, in relation to medical education and research, must familiarize themselves with and learn more about man's phylogenesis, both organic and social, and man's ontogenesis, biological, psychological and social. He must understand man's basic needs and his means of adaptation in a physical, organic and social environment. He must study the failures of adjustment and define more

clearly their determinants and what constitutes meaningful stress. And finally, he must study and devise new and more effective means of aiding the adaptive efforts of the sick patient.

With these words, Engel has summarized the task of psychoanalysts as they bring their science to academic medicine. Likewise, the benefits to the psychoanalyst-teacher in medicine of broadening his perspective to include the understanding of the factors mentioned above will permit the fuller fruition of experimental knowledge concerning man's development and behavior and in consequence, a broadened application of the principles developed by Freud and his followers.

All that has been discussed above has been focused largely on the task of general medical education. This includes the medical student and the non-psychiatric intern and resident, as well as non-psychiatric faculty. What of the resident in training in psychiatry and of psychoanalytic training in its fullest sense of residents and faculty members? I draw your attention to an excellent discussion by Maurice Levine in a book entitled, *Twenty Years of Psychoanalysis*.⁴ The title of his paper is, "The Impact of Psychoanalysis on Training in Psychiatry." In his presentation and the discussions by Henry Brosin and Roy Grinker each essayist indicates the tremendous impact that psychoanalytic concepts have had on training of specialists in psychiatry. As Levine puts it, "An essentially static and descriptive discipline has become dynamic and vital and energetic. Psychoanalysis has played an outstanding part in the transformation, but it has not been the sole agent of the change." The major concern for the balance of Dr. Levine's paper concerns the matter of the training of the psychiatric resident for maximal integration of psychoanalytic insights which are pertinent to dealing with the broad gamut of illness faced by the general psychiatrist. He discusses in detail the essential components and differences of the psychoanalytic psychiatrist from the fully trained analyst, including the subject of wild analysis, its dangers and the need for derivatives of psychoanalysis that can be applied in a broad range of illness.

No attempt will be made here to discuss

³ Edited by Roy R. Grinker. Published by Charles Thomas, 1953.

⁴ Published by W. W. Norton & Co., 1953.

the integration of formal and complete psychoanalytic training into the university framework. Examples of this development are well known and new patterns are continuously developing throughout the country.

Many of you may be wondering what pertinence the material I have presented has in a section on psychotherapy, whose general topic is reintegration of psychoanalysis into psychiatry, with the specific title of, "Reintegration Into Teaching." It is my thesis that a scientific understanding and approach to treatment of patients through the personal contact of one person, the physician, with another person, the patient, is the province of all physicians. Thus, the underlying principles involved in the forces which make for improved adaptation of the ill person requires an understanding of the total. If we are to bring the benefits derived from our understanding of human development, human adaptation and human maladaptation as developed and understood by psychoanalysis to the masses of the people, it is essential that a synthesis of all of the factors described above and outlined by Engel become a familiar component of every physician's conceptual framework and

modus operandi. Obviously, every medical student or every non-analyst cannot be a psychoanalyst. However, every medical student and every non-psychiatrist and every non-analyst can have a grasp of the forces involved in human health and illness, which make it possible for him to understand, to tolerate and to maximize the use of the facts of transference and countertransference often described as the "tincture of physician" in a scientific manner. Thus, that which has been described as the essence of the true physician, and which has previously been described as an art becomes more scientific and more controllable. All of the above, the strivings toward means of introduction of psychoanalytic concepts into medical teaching, as well as into the teaching of psychiatrists, has as its goal the enriching of our understanding of the total operation of man. This is in the direction of creating what I like often to refer to as a science of the art of medicine. By this means, over time, can our understanding of the many factors involved in human health and illness be elucidated and can psychotherapy in its broadest sense become increasingly available as a standard aspect of medical care.

A GRADUATE SCHOOL FOR PSYCHIATRIC EDUCATION OF PHYSICIANS IN MENTAL HOSPITAL SERVICE¹

PAUL H. HOCH, M.D.,² AND SANDOR RADO, M.D., D.POL.SC.³

In 1958, after years of experimentation, the New York State Department of Mental Hygiene authorized the establishment of a new graduate school—The New York School of Psychiatry—as a pilot center for the psychiatric education of residents in a group of state mental institutions in the Metropolitan area. Chartered by the Board of Regents of the University of the State of New York this school operates under its own Board of Trustees, its own officers of administration, and an Advisory Committee, headed by the Commissioner of the Department of Mental Hygiene. The group of state institutions associated with the New York School of Psychiatry (Brooklyn, Central Islip, Creedmoor, Kings Park, Pilgrim State Hospitals; Willowbrook State School)⁴ have at present a total bed capacity of 36,000 and 126 positions for residents.

The School is quartered in Manhattan State Hospital (Ward's Island) in New York City. Teaching facilities include administrative offices, lecture, seminar, and conference rooms, a library and an outpatient clinic. It has a faculty of 20, a clinical faculty numbering 15, and some 20 visiting professors and guest lecturers. Its student body at the start of the academic year 1959-60 numbered 77.

A word of appreciation should be addressed to the Directors and administrative personnel of our associated hospitals. Their readiness for close collaboration was as

generous as their willingness to facilitate and expedite a teaching schedule that impinged on their own schedules for patient care.

From the point of view of the planners it proved to be less difficult to construct a new unit charged with a single task (to educate residents in a uniformly operated Mental Hospital System) than to add the same task to the multiple responsibilities of a large academic center.

To satisfy both scientific requirements and practical necessities,⁵ graduate psychiatric education was divided into 2 stages. The over-all plan, stage 2 of which is not yet fully operative, is shown in Table 1(2):

TABLE 1

THE 2 STAGES OF GRADUATE PSYCHIATRIC EDUCATION

1. *Basic Curriculum.* This embraces the entire field of psychiatry, requires 2 years and is combined with residency in a mental hospital. Followed by:

2. *Advanced Curricula.* Specialized training in the following areas:

1. Administrative Psychiatry (hospital and community); 2. Medical Psychotherapy, including (2a) Medical Psychoanalysis; 3. Psychiatry for the Aging; 4. Child Psychiatry; 5. Mental Deficiency; 6. Methods and Techniques of Research Psychiatry.

Areas 1, 2, 3, 4, and 5 require 1 year each; areas 2a and 6, 2 to 3 years each. Whichever area is selected, all advanced curricula are combined with work at a psychiatric institution.

Our first responsibility in the basic curriculum is to demonstrate to the student the fundamental significance of the scientific method. The student must learn how to think. In his clinical observation, he is taught to give full consideration to informa-

⁵ For background information see Whitehorn (1).

³ Dean, Professor of Psychiatry, The New York School of Psychiatry.

⁴ Arrangements for the graduate psychiatric education of residents are made by the Department of Mental Hygiene according to geographical location. Another group of state mental institutions is connected with the Department of Psychiatry of Columbia University, and a third group with the Department of Psychiatry of the State University Upstate Medical Center in Syracuse.

tion derived from the basic sciences. The days of crude clinical empiricism are gone. To become a competent clinician, grounding in the basic sciences is essential. Nor should the student indulge in the perpetuation of outworn and sterile dogmatic concepts. He is expected to develop and refine his own scientific judgment, upon which the scientific value of his future work depends. In order to bring basic science instruction closer to the student's clinical experience, whenever feasible, patients are used for the demonstration of theoretical principles and experimental findings. The outpatient service plus the patients in the associated hospitals assure the School access to an almost unlimited variety of psychiatric disorders.

The basic sciences of clinical psychiatry fall into two groups; one psychodynamic, and the other, physiological. The former uses chiefly the investigative methods of communicated introspection; the latter, the manifold investigative methods of inspection, culminating in measurement by yardstick and clock. To facilitate correlation of the emerging 2 conceptual schemes, both are presented within the same adaptational framework. Every effort is then made to confront the facts and theories of psychodynamics with the corresponding facts and theories of physiology, and vice versa. Only by such cross-interpretation can one hope to diminish the confusion arising from the fact that the physician is compelled to use 2 approaches to the understanding of the same human organism. Without psychodynamics basic research in psychiatry has no problems—and without physiology, no solutions(4).

Instruction in the physiological sciences centers upon genetics; structure and performance of the brain; neurochemistry. Instruction in adaptational psychodynamics (3) deals with the part played in behavior by the societal as well as organismic mechanisms of motivation and control.

In the attempt to present a balanced and integrated scientific picture of human behavior, the essential determinants of behavior are thus traced through the levels of molecule, cell, organ, organ-system, individual, family, wider social groups, mankind as a whole, to the emergent patterns of

cross-level integration.⁶ From healthy, or adaptive behavior, the curriculum proceeds to the impairments and failures of adaptation known as the psychiatric disorders. Instruction in clinical psychiatry includes courses on examination, pathology, diagnosis and therapy. There are also courses on applied psychiatry and general subjects including methodology.

To be prepared for psychodynamic work the student needs to be sensitized to motivational understanding by training in self-awareness. As Freud has demonstrated, behavior disorders are dominated by hidden motivation. The student cannot possibly uncover the patient's hidden motivation, unless he has first learned to understand his own hidden motivation. While individual preparation of each student psychiatrist—such as an up-to-date personal analysis(2)—is an obvious practical impossibility, classroom instruction in "psychodynamic sensitization"⁶ (carried out in conjunction with interviewing patients, discussing dramatic events and stories, *etc.*) meets the conditions of graduate education in the entire field of psychiatry. But it leaves one problem still unsolved: how to open up for the student (who has had no personal analysis) his own life experience as a psychiatric resource. Adolf Meyer's early experiment to have each student write and explore his autobiography failed to achieve this purpose.

Alongside the various phases of preparatory and theoretical instruction, demonstrations are given of interview techniques, psychological testing, and the techniques of the diverse treatment procedures. This phase of practical instruction is followed by weekly clinical conferences in which each student in turn interviews a patient in front of the class. The patients selected are under treatment either in the outpatient clinic or in the hospital. The purpose of these conferences is to explore the patient's entire pathology (physiological as well as psychodynamic) to determine diagnosis, prognosis, and the treatment method to be employed, and to evaluate the therapeutic results. The student is exposed to a prolonged and closely supervised practical experience, both with psychoneurotic patients in the out-

⁶ See Rado's statement(5).

patient clinic and with psychotic patients at the hospitals.

The psychiatrist is concerned with the disordered "psyche" as it expresses itself in behavior disorders. Hence, all psychiatric treatment procedure—pharmacological, hormonal, electroconvulsive and other—must be employed in an appropriate psychotherapeutic framework. In recognition of this fact, a special course is devoted to the subject of "Adaptational Theory of Treatment: psychotherapeutic motivations and psychotherapeutic techniques." At the outpatient clinic, the student's chief tasks are to conduct admission interviews and practice psychotherapy. However, we are now in the process of introducing combined treatment methods, which supplement psychotherapy with drugs tested at the research installations of the Department of Mental Hygiene.

The diagnostic and therapeutic work of the students at the outpatient clinic of the School is supervised by a faculty member who interviews every patient assigned. Furthermore, members of the teaching staff visit once weekly each associated hospital, supervising the therapeutic work of students with patients at their "home" hospital.

Although the unifying concept of the school's educational plan is adaptational psychodynamics, the students are exposed to other frames of reference as well. Fifteen lectures, given by visiting professors and

lecturers, present the original historic version of Freud's theories and the more recent psychodynamic formulations of all schools. The same is true of the different schools in the physiological sciences. Throughout the curriculum, reading seminars cover the extensive literature of psychiatry. In this way, the many avenues of psychiatric thought are opened to the student for his own appraisal and evaluation.

A summary of the basic curriculum is shown in Table 2(6).

A certificate is issued to the student after successful completion of the basic curriculum.

In 1959, three advanced curricula in the following specialized areas were opened up:

1. Administrative psychiatry (hospital and community);
2. Medical psychotherapy;
3. Psychiatry for the aging.

The advanced curricula, too, are given twice weekly, except the one in medical psychotherapy, which requires attendance at the outpatient clinic of the School 3 times weekly.⁷

As residents in the associated state mental hospitals, students receive living accommodations and an annual salary of from \$5,850 to \$6,530 per year. No tuition or other fees are charged for either the basic or advanced curricula or the survey course.

Finally, a few words about the admissions procedure. The prospective students file two applications—one for admission to the New York School of Psychiatry and another for appointment as residents in the associated state mental hospital of their choice. It is hoped that the associated hospitals will be able to fill the residencies with applicants who also meet the admission requirements of the School. The general plan of instruction shifts the emphasis from preparation for private practice to preparation for public service in a mental health institution. In this way the Department of Mental Hygiene hopes that the School will perform

TABLE 2

SUMMARY OF THE BASIC CURRICULUM

<i>Theoretical and Clinical Instruction</i>	
Basic Sciences	
13 courses	185 hours
Clinical Psychiatry	
15 courses	375 hours
Applied Psychiatry	
3 courses	17 hours
General Subjects	
9 courses	147 hours
<i>Supervised Work</i>	
At the School's Outpatient clinic ..	317 hours
At the Students' Home Hospital ..	152 hours
Total	1193 hours

In addition, the student has to fulfill the requirements of residency work at his home hospital.

⁷ In the near future 3 more advanced curricula will be added, one in child psychiatry, another in mental deficiency and a third in the methods and techniques of research psychiatry. In time it is hoped that the program in medical psychotherapy will be broadened to include a complete special course of training in medical psychoanalysis.

an all-important recruiting function for the State Mental Hospital Service. How many of our graduates will continue in State service remains to be seen. Outstanding graduates are given faculty appointments.

Recently, the scheme of basic and advanced curricula was supplemented by a survey course which requires one day a week throughout one academic year. It offers students a series of lectures and conferences in subjects fundamental to the hospital practice of psychiatry. This course is open to any medical-staff member of an associated hospital upon recommendation of his director.

The Department seeks to raise the professional level of its hospitals by systematically improving clinical research and treatment programs. The establishment of this graduate school attempts to insure for the

future of the associated hospitals an adequate supply of scientifically trained and fully competent physicians who will be able to keep pace and actively participate in the scientific advances to come.

PROGNOSTIC FACTORS IN SCHIZOPHRENIA¹

WERNER SIMON, M.D., AND ROBERT D. WIRT, Ph.D.²

European psychiatry, under the strong influence of Kraepelin(4), employs conceptual and methodological differences from those used in the United States, in the diagnosis, symptomatology, treatment and prognosis of schizophrenia. The rate for lasting social recovery has been quoted as approximately 40% by various American and European investigators. Several factors have been considered by Langfeldt(5, 6) as indicating a favorable prognosis in schizophrenia. Among these are: an emotionally and intellectually well-developed pre-psychotic personality; demonstrable precipitating factors; acute onset; affective admixture; and favorable environment before and after the onset of the disorder. Investigations of the natural history of schizophrenia in this country by Hastings, *et al.*(3), have shown that 60% of all patients spent over half of their initial post-hospitalization interval in a mental institution or experienced severe adjustment difficulties which necessitated continuous care by their families. Long-term follow-up studies by Staudt and Zubin(12) have failed to show better results for the treated over the untreated in terms of recovery and improvement, with the recovery rate remaining around 35 to 40%, although the treated groups' stay in the hospital is definitely shortened and the death rate is lower in this group. It has been claimed by Donnelly and Zeller(2) that the best remission rates are achieved in disorders which are episodic and self-limiting in time, either remitting spontaneously or responding to therapy. Schofield and Balian(8, 9) have shown presumed etiologic factors to be about as common in normals as in patients diagnosed schizophrenic. If better prognostic indicators were available, results of differential therapies could be evaluated more adequately(10, 11, 13).

METHOD

In this investigation, personality, historical and demographic data of 80 consecutive first hospital admission patients with clearly established diagnoses of schizophrenia were studied. In addition, the following 4 social history variables, taken from a factor analytic study by Beck and Nunnally(1), were employed: 1. Parental rejection; 2. Absence of consistent parental figures; 3. Parental indifference or inadequacy; and 4. Parental over-protection. Each of these factors was rated for 5 traits having the highest factor loadings. Twelve prognostic factors, reported in the literature as having validity, were used. These were taken from studies by Pascal, *et al.*(7), and by Schofield, *et al.*(8, 9), and include the following factors:

TABLE 1
PROGNOSTIC FACTORS

1. Affective Expression.
2. Orientation.
3. Direction of Aggression.
4. Type of Onset.
5. Duration of Illness.
6. Precipitating Stress.
7. Marital Status.
8. School Deportment.
9. Marital Adjustment.
10. Presence of previous episodes.
11. Adjustment to the hospital.
12. Presence of ideas of reference.

The most (15) and least improved (13) patients were compared clinically and statistically during hospitalization and the most (26) and least improved (25) were similarly studied 1 year following hospitalization, to determine which factors were prognostic of hospital course, and which were related to longer term adjustment.

RESULTS

At the time of discharge from the hospital, 3 of the prognostic factors showed discrimination between those who improved and those who did not. We found that exaggerated expression of affect, rapid onset of symptoms, and a brief rather than an ex-

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² VA Hospital, Minneapolis 17, Minn.

tended period between the acute onset and hospitalization, are all prognostically favorable indicators at a statistically significant level. Insidious onset, accompanied by blunted emotional life, and a period of years between the first symptoms and the first treatment efforts were found to be prognostically unfavorable signs.

Nearly all the patients in both groups were oriented at the time of their admission to the hospital. Most expressed aggressive feelings outward rather than toward themselves; most had experienced only mild precipitating stress; and most had some history of previous episodes of disturbed behavior, not diagnosed as schizophrenia, however. In nearly all categories differences were in the expected directions, even though most were slight.

We found no reliable differences for such demographic data as age, ordinal position in the family, number of siblings, educational level, religion, socio-economic status, number of children, and incidence of mental illness in the family.

Only 2 items among the social history factors differentiated the groups at admission, and thus predicted from their social histories the outcome of hospital treatment. These were: "Absence of consistent parental figures", which predicted poor treatment response, and "Mothers would do anything for the child," which heralded favorable outcome. Other factors which showed a trend toward distinguishing the backgrounds of the patients, indicate that more of the improved patients came from homes in which mothers struck out in anger, rather than maintaining constructive discipline; and more of the unimproved patients lacked any real parental figure or lived with parents whose discord left the family in a turmoil and whose fathers were promiscuous and debauched. These findings suggest the importance of the presence of parents in the home, and that consistent discipline is less important than protection, family stability, and positive relations between the parents.

In comparing patients who improved during a course of hospital treatment with those who did not, we found several distinguishing characteristics. Patients who did not improve were men who at admission

were markedly psychotic, who evidenced defective functional intelligence, who were dilapidated, regressed, and apparently dull in affect. They exhibited a relative blunting of emotions and had an insidious onset of illness with a poor work history. Their early background was characterized by family discord or isolation from parental influence.

One year after hospital discharge, all improved patients expressed some religious affiliation, whereas half of those having no affiliation were in the unimproved group. Patients who maintained their improved status a year after hospital treatment were individuals who tended to express their aggressive impulses, rather than turning them inward; who had an acute onset of schizophrenia, which had a duration of a month or less prior to hospitalization; who were married and had a good marital adjustment; who did not have a history of previous episodes of severe emotional disturbance; and were management problems while hospitalized. The patients rated as unimproved at the time of the follow-up were men whose histories showed an insidious onset of illness, developing over a period of 2 years or more; who were not hospitalized until several years following onset of symptoms; who were single; and who showed some evidence of periods of emotional disorder in earlier life.

Since the statistical analyses showed few clear prognostic or social factors to be significant in differentiating improved from unimproved schizophrenics, we attempted a clinical comparison of the 7 most improved and the 9 patients least improved, utilizing detailed social histories. On the basis of this comparison, 13 behavior variables, both favorable and unfavorable, were found to differentiate good and poor prognosis in schizophrenia. These are listed in Table 2.

Items 5, 6 and 7 were characteristic of every one of the poorest outcome patients. The other items were far more frequent in patients with poor follow-up ratings than in those with good outcome. The 3 items characteristic for good prognosis were found in all of the best outcome patients and in none of those with poor follow-up ratings.

In addition, a number of similarities appeared, which we believe are diagnostic or predictive of a schizophrenic disorder,

TABLE 2

BEHAVIOR DIFFERENTIATING GOOD AND POOR PROGNOSIS IN SCHIZOPHRENIA

Poor Prognosis :

1. No behavior problem in school or at home.
2. Lack of socialization during childhood (poor relations with both peers and siblings).
3. Threatened (without cause) by parents as a form of discipline.
4. Poor heterosexual relationships throughout life (no interest in girls; fear of girls).
5. Few interests during adolescence and early adult life.
- *6. Poor work history throughout life.
7. Inability to express aggression throughout life.
8. Possible organic involvement (instrumental and/or premature birth; infectious process; head injury, etc.).
9. Inability to express feelings ("difficult to get to know").
10. Fears associated with school and/or peer relationships.

Good Prognosis :

1. Some specific traumatic episodes which might have precipitated onset.
2. Good work history during childhood and adolescence.
3. Marriage (with or without conflict).

and which were common to both improved and unimproved groups. Common among both extremes in improvement rate was a history of over-ambition. As children and adolescents many had an ego ideal with whom they attempted to identify. This was usually a father whose achievement the sons could never match. If the father was a physician or a bricklayer, their sons who also became physicians or bricklayers were never quite successful or skillful. Prior to adolescence many of these patients had made a single important achievement, such as winning a trophy or becoming the local athletic hero. Throughout life these men were identified in the community as persons who had achieved some special distinction in early life, a distinction they could never recapture. Most of the patients were described as shy and withdrawn while children. They were considered sensitive and fragile by their families. Many of them suffered from a variety of psychosomatic

symptoms. During and after adolescence they tried to break away from home. Some took jobs, some went into service early, and some also ran away from home. This often coincided with an attempted change of interest pattern from that set by the father. In all cases these efforts failed and the patients returned home; many were troubled with feelings of guilt and self-blame for their non-achievement. Usually the onset of schizophrenia was displayed in acute paranoid behavior either in service or shortly after discharge. After service they generally showed increased apathy and lack of striving, marked weight loss, few interests, and surrender to schizophrenic thinking.

Families of these patients were characterized by fathers described as heavy drinkers and harsh disciplinarians. The mothers also were described as strict, seemingly unhappy most of their lives and complained of poor health. Patients rated as unimproved frequently had schizoid tendencies most of their lives, while the more improved patients were more likely to have shown some greater rebelliousness during adolescence. The more improved patients suffered some reaction to interpersonal threat (e.g., the death of a parent) during adolescence, while the unimproved patients were likely to have had similar experiences much earlier in life.

DISCUSSION

Our data regarding prognostic factors failed to support most of the findings of Pascal and his co-workers(7). Our findings, however, do confirm some of the factors listed by Langfeldt(5, 6) as indicating a favorable prognosis in schizophrenia. Langfeldt has pointed out that precipitating factors are as a rule lacking in typical cases of schizophrenia, but that in atypical, schizophreniform conditions psychogenic traumas are frequently observed. He emphasizes that such atypical schizophrenias should be grouped and classified as schizophreniform psychoses, and he recalls his personal observation that half of the patients diagnosed as having schizophrenia in the United States would be classified differently in Europe. Langfeldt believes that research in schizophrenia should be concerned predominantly with process schizophrenia, and that it has

been quite detrimental to the progress of psychiatry "to let the whole dementia praecox idea be absorbed by the collective designation of schizophrenia."

Our clinical appraisal of the histories of the most improved and the least improved patients showed a number of characteristics typical of both extremes. These findings reveal that schizoid personality traits were evident from early life. A few social influences appeared to have favorable prognostic value; chiefly an adequate work history, some effort at heterosexual adjustment, and the presence of precipitating stress. These factors suggest that the distinction between improved and unimproved patients may be based on a fundamental difference between reactive and process forms of schizophrenia, and support the view of those who hold that such a diagnostic distinction has merit.

SUMMARY

Four social history and 12 prognostic factors, reported in the literature to have statistical validity, were studied in this investigation. In addition, personality, historical and demographic data of 80 consecutive first hospital admission patients were compared clinically and statistically during and 1 year following hospitalization.

Some factors were prognostic of hospital course, while others were related to longer term adjustment.

A clinical comparison utilizing detailed social histories of the most and least im-

proved patients, produced 13 behavior variables, both favorable and unfavorable, which differentiated good and poor prognosis.

In addition, the data give empirical support for some theories of etiology in schizophrenia.

THERAPEUTIC DEVELOPMENT AND MANAGEMENT OF AN ADOLESCENT RESIDENTIAL TREATMENT SERVICE IN A STATE HOSPITAL¹

JAMES F. SUESS, M.D., AND ARTHUR Y. HOSHINO, M.D.²

The treatment of adolescents in an adult state mental hospital has become an increasingly complex problem. At Warren (Pennsylvania) State Hospital, the number of such patients under the age of 20 years admitted with functional psychiatric illness other than sociopathy has risen from an annual rate of 10 in the 37 years preceding 1950 to 28 in 1959. In addition, generally, these patients were more seriously ill than adults.

Although there is a large children's unit in one of the state mental hospitals, its facilities are sorely overtaxed and admissions are slow. Also the great distance of this unit from our geographical area has made parents unwilling to send disturbed children there, and instead we find these children admitted to our hospital for care.

Our experience has indicated that it is a fallacy to expect these children to adjust better to an adult ward than to one designed specifically to meet their many different needs. These children cannot be expected to develop a more integrated personality by identifying with adult models who are themselves grossly disturbed. The children lack normal heterosexual social experiences in the usual adult ward, making later social adjustments difficult. Also, if they are to be adequately rehabilitated, they must continue their education and such facilities are completely lacking in the usual adult state hospital. Additionally, the social goals of the adolescent differ greatly from those of the adult and therefore even normal adolescent behavior would not be tolerated by the patients or attendants on the usual adult ward.

Identifying these needs we developed the present adolescent unit in our hospital, making use of existing facilities and personnel.

An attempt was previously made to establish a small unit for grouping 7 or 8 adoles-

cent girls, but this effort ended in failure after only 2 months. There was, in retrospect, a lack of active support by the upper echelon of medical, nursing and administrative personnel, and a lack of understanding and interest on the part of the involved nursing and attendant groups with inadequate communication of the aims and goals to them. In addition, there was a poor selection of patients in that 40% were sociopaths. Also, the use of unsuitable living quarters—a small dormitory in a large ward of middle-aged women—resulted in daily friction between the children and adults, both patients and attendants. Finally, there was an absence of a structured adolescent oriented program. Instead the adolescents were fitted into the daily routine of the adults in more or less random fashion.

Therefore, in September, 1957, when we proposed the opening of the present 10-bed units, one for boys and one for girls, we were met with considerable resistance. There were fantasies expressed of wholesale destructiveness and feelings that the overt behavioral problems of these adolescents would be geometrically increased by their being concentrated in one area rather than being diluted through several adult wards.

SELECTION OF PERSONNEL

The employee complement consisted of one psychiatric attendant per unit on each working shift under the full-time supervision of a third-year psychiatric resident physician and all responsible to a staff psychiatrist. Since these people would work intimately with adolescents and participate in much of their activity, a decision was made to use only persons under the age of 40 as they would be more physically active, tend to be less emotionally rigid and biased, and have fewer pre-conceived ideas of normal or abnormal adolescent behavior. The possibility that the adolescent group might activate latent personality problems in the employee was also considered in the choice; despite

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Warren State Hospital, Warren, Pa.

this, after 3 months, it was found necessary to transfer one of the male attendants to another area after he became unduly concerned and covertly punitive to a boy who engaged in transient masturbatory activity.

The various employment practices also created problems. The regularity of 3 employee shifts a day produced irregularity in the concept of father and mother figures. Also the turnover in state hospital employees at times was quite rapid and could give rise to further difficulties in establishing the stability of parental surrogates. Fortunately, we have maintained the day and evening personnel almost unchanged throughout. The modern custom of the 5-day work week posed another stumbling block; this was handled by having the replacement days occur on week-ends when the adolescents were more likely to be visiting away from the hospital.

SELECTION OF PATIENTS

Initially, there were few limitations on the selection of patients and as a result we were frequently confronted with over-zealous attempts of the professional staff to incorporate within the adolescent group young adult patients over the age of 19, who were "emotionally just children." Several of these individuals were tried in the unit without success, not only because they were physically, experientially, and educationally more mature, but also because they were offended by the daily activities which fitted the needs of the adolescent. The severe and obvious sexual deviant was initially brought into the program, but found disrupting. Patients who had sociopathic personality disturbances, primary mental deficiency, and those with organic brain syndromes were also excluded. Found to be treatable in our unit were adolescents with schizophrenic reactions, neurotic disorders, character disturbances (primarily passive-aggressive), those with lowered I.Q. on the basis of interfering factors of an emotional nature, and those in whom sexual maladjustment was clearly secondary to other functional illness.

It soon became apparent that a necessary part of the intake policy was to have interested parents or parental figures outside the hospital in regular contact with the patient, psychiatrist, and social worker to work

through parental roles in the disintegrative factors operating and plan for the patient's future.

Several admissions were refused on this basis; surprisingly enough one case was that of a boy with a character disorder referred by a county juvenile court which refused to accept the expense or responsibility of appointing the juvenile agency to work with the patient and hospital. There was also in many instances the problem of travel for these parents in view of the area which this hospital served, the outer limits being over 125 miles.

USE OF AVAILABLE HOSPITAL FACILITIES

Immediately available hospital facilities consisted of 2 small wards of 10 beds each at opposite ends of a very large building, housing male patients in one half and female patients in the other. Although we would have preferred the 2 wards to be adjacent, the existing structure made this physically impossible. However, children were treated as a coeducational unit, except for the actual ward living-sleeping situation.

As the children improved, hospital shops such as the garage, plumbing, electrical, radio, paint, woodwork were offered to individual children as apprenticeships. Nurses' aide and home economics courses were devised by the nursing staff for some of the girls and a special agriculture course by a farm and ground supervisor for some of the boys. A coeducational class-room was formed for elementary teaching, staffed by part time volunteer certified teachers.

A problem was immediately created by the wide range of educational needs of the children. In conference with the teachers we found the best approach was in the use of a basic educational core of remedial reading as needed, along with social studies, general science, some math, art, and news-writing assignments for the hospital weekly newspaper. The psychiatric aides were used as class-room assistants and to continue certain assignments. In the beginning we had serious doubts that the adolescents' attention could be directed for more than 30 minutes in formal class-room work and so limited the time. We soon found to our surprise that this was an error and accordingly lengthened the class-room time to 2 or 2½

hours without difficulty. The recreational and occupational therapies occupied additional hours weekly so that the children were engaged in crafts, sports, dancing, parties, band, chorus, and other group activities. Parenthetically, some of these activities were carried on in the family atmosphere of the homes of some of the staff.

COMMUNITY FACILITIES

One of the guiding principles in the program was to place the patient into normal adolescent activities, and as much as possible, with normal adolescents. Consequently, we utilized many of the community facilities available in Warren, Pa., a small town of 15,000 about 3 miles from the hospital. For example, the patients belonged to the local Boy Scout and Girl Scout Area Councils, had their own troop, attended the area Scout Camps throughout the year, joined in the County Jamboree, Explorer Scouts, and related activities. To our knowledge the hospital Boy and Girl Scout troops were the first of their kind in the country. The adolescents were also part of the county 4-H group and were involved in some of their congregate activities.

The community recreation parks, state parks, roller skating rink were used and in addition, the Y.M.C.A. swimming pool. Opportunity was also given to attend the dramatic play series, concerts, basketball and football games. These activities were interspersed through the month in an amount similar to that of an active adolescent. Nevertheless, many of the patients did say that they had learned to do more things in residence than ever before in their lives.

During the last year, as a result of excellent cooperation and liaison with the local Junior and Senior High Schools, we enrolled a total of 8 children in the 8th to 12th grades, taking a general academic course. These patients rode the school bus to and from school, bought lunch in the school cafeteria, were involved in extracurricular activities, and got their notices in the school paper. One patient graduated from high school last year and 2 more are now in their senior year. With special dispensation, these adolescents were allowed to start classes at such time during the year as their emotional and educational status permitted and when

they left the hospital, credit was transmitted to the home school. In the future we foresee a greater number of children attending the public school system.

The area State Vocational Rehabilitation Officer has assisted in utilizing local industry for apprenticeship and on-the-job training for some of the older adolescents while in residence. Recently a 19-year-old girl learned the skilled industrial art of china and pottery striping and left the hospital to be self-supporting.

Additional community participation was arranged through the invaluable aid of the hospital Volunteer Service by enlisting service and materials from individuals, clubs, groups, and County Mental Health Associations. The volunteers have been able to provide spending and school lunch money as needed, radios, washing and sewing machines, clothes, books, school equipment, and several retired school teachers to conduct basic education on the hospital grounds. One recent innovation for the children who attend community schools has been providing community sponsors, usually the parents of other adolescents in school. Such sponsors assumed guidance for these patients when they attended in the community invitational group, school, or adolescent social functions, which occurred in the evening or on the week-end.

MANAGEMENT EXPERIENCES

After 2 1/3 years experience in the operation of adolescent residential treatment units, the following observations are offered. We have found that the successful development of a therapeutic milieu evolves only after careful planning. Initially, there must be active support of the ward personnel by the staff which should begin before the unit is operational and then be followed by group and individual conferences with all interested personnel to maintain unanimity of direction and purpose. Psychiatric aides who have functioned well with adult patients frequently are bewildered when dealing with children; this poses a threat to the aides and their problems are handled by daily individual and bi-weekly group conferences. Frequently too many well-meaning personnel on the periphery try to become involved by "wanting to do things"

or literally trying to adopt the wards temporarily as if they were a new kind of hospital toy. The effect on the patient is similar to that on a child whose competitive parents vie for his favor, and the patient is overloaded with intrusive affective experience.

Next, there must be a well-defined structured program for the guidance of ward personnel and not a vague schedule in a hit or miss fashion. Our early experience in which we tried an extemporaneous schedule was most damaging, with the children frequently complaining of boredom and the personnel of lack of perspective. Also our attitude about patient control is now much more fluid than at the outset, in that more responsibility is gradually given the patient when this is beneficial, *e.g.*, in community school attendance, individual and group participation in adolescent community social events, and week-end or short-term visits at home. The latter item is of great importance inasmuch as the patients showing slower recovery tend to be those with disinterested parents who make infrequent visits and seldom take the child home. In contrast, when the adolescent visits at home, he very frequently dispels the family's fear that he cannot or will not recover and this promotes a stronger family union. Visits with the parents, whether in the hospital or at home also relieve the adolescent's fear of being abandoned and forgotten.

We feel the hospital education program by the volunteer teachers functions best when it is not too complex. Our experience has shown that a large percentage of severely disturbed children have serious reading impairment. Thus, primary emphasis was given to remedial reading followed by general classes in social studies. Dramatics, newswriting, hospital library assignments, and individual tutoring were also used. For children attending community schools, a staff member held conferences with the student and the school curriculum or guidance counselor to arrange the school program. It is our feeling that education is the function and responsibility of the school and except for the pertinent psychiatric evaluation which we supplied, we have never interfered in the school's prerogatives with the students. Later through subsequent bilateral

conferences, many incipient or fantasied difficulties were alleviated.

The more classic forms of psychiatric treatments were not neglected. Although electroshock and insulin coma therapies were not used during residence in the unit, the various tranquilizers were frequently administered; their use tended to be more confined to the older children. Great importance was placed in psychotherapy, in that all the patients received group therapy 3 hours per week throughout residence. Initially the children were seen in 2 groups divided according to age. Later we found it more successful to have one group for boys and one for girls, meeting on their own wards with the ward attendant included as an integral member. The discussions centered around the "here and now" events on the ward, at school and at home with individual and group transference manifestations being interpreted by the leader or the group members. Almost half of the adolescents received individual psychotherapy averaging about 2 hours per week. However, we found that both group and individual psychotherapy was best managed by the psychiatric staff or by the most senior residents. Early attempts in which supervised junior residents handled groups or individual cases frequently ended with that resident asking to be relieved or feeling quite helpless. This situation invariably occurred when these severely ill children did not respond to the supportive or analytically oriented types of therapeutic approach that the resident was learning to use with adults. Generally in either group or individual psychotherapy little attempt was made to uncover threatening unconscious material. Instead emphasis was placed on establishing the adolescent's self integrity as a person, as well as discussing the past and present models used as a basis for this.

Two final observations should be noted. We strongly feel that such a program should be conducted coeducationally and finally that the problem of destructive activities does not exist. With unlimited opportunities to damage furniture, and other equipment, the 2 1/3-year toll has been a few window panes and one toilet plugged with a roll of paper. No activity or property has ever been withheld because of fears of damage. In

short, if the adolescents are not expected to be destructive, they apparently will not be. This appears also to be due to the patients helping each other, especially with the ones more sick, and using an internal group pressure to draw the more disturbed patients forward and control destructive behavior.

SUMMARY

A total of 47 adolescent patients (26 males and 21 females) were treated in our units in 2 1/3 years of operation. This total includes those patients previously mentioned who were subsequently found to be untreatable. There were 39 schizophrenics, 4 neurotics and 4 character disorders. Disposition of the patients did not significantly differ according to the sexes: 24 left the hospital as improved. These patients spent an average of 8 months (range 3 to 22 months) in the units. Sixteen adolescents are now in the units in active treatment and have spent an average of 11 months there (range 1 to 27 months). Seven patients were transferred unimproved to other parts of the hospital after spending an average of 12 months (range 1 to 23 months) before transfer.

The 7 treatment failures were characterized as follows: Two patients were completely uncommunicative, one on the basis of organic damage, the other being severely autistic from early childhood. Two patients were in fact too old for the unit, being 20 years or over. One patient was a homosexual sociopath. One patient regressed to the point of being a completely infantile nursing problem who could not be adequately cared for in these active units. Finally, 1 of the older adolescents, having shown some definite improvement after 1 year, reached a plateau with little further change and was transferred to the insulin unit for further treatment.

It is our opinion that an adolescent unit is a necessary part of any adult state hospital which admits these emotionally disturbed patients. We feel that a unit such as ours can be established wherever there is interest in the care and treatment of the adolescent, by making full use of available hospital milieu and community facilities.

This presentation was not intended to contain the dynamic transactions and interpersonal operations of the patients and per-

sonnel in the units or of the parents and the hospital staff. This will be the subject of a later report.

DISCUSSION

JOSEPH E. BARRETT, M.D. (Knoxville, Tenn.).—The authors' presentation certainly points up the need for good pre-operational planning, programming and selection of personnel in this highly special psychiatric field.

We developed a similar unit at Eastern State Hospital in Williamsburg, Virginia, with many of the trying conditions and situations mentioned by the authors.

The selection of adequate living and activities quarters is of major importance. The selection of the strongest and, as nearly as possible, indestructible quarters should receive top priority. In our experience these patients are much more destructive than the usual adult mental patient. This is not always because of overt destructive tendencies but because of a tendency to greater physical activity than is seen in the usual adult patient. If we think for a moment that these youngsters are going to sit quietly in a day space until called upon or that they are going quietly to bed at 7 or 8 o'clock and sleep until morning, we need to revise our thinking.

The program of supervised activities should be well worked out for a full day until around 10:00 P.M. The continuation of their schooling is most important and we have found the Department of Education both interested and helpful. In the program at Williamsburg they were most co-operative in supplying much of the material and even some of the full time teachers who were specially selected with their approval, and this gave the school program an accredited status. This is especially beneficial when the patient is ready to return to the regular public school system. We tried for a while to have some of these children go to the local public schools but had to give it up because of some complaints. There is still a feeling of contamination by some when coming in contact with anyone from a mental hospital.

We found that for a while at least school work had to be done with these children on an individual basis. So it is fortunate indeed when the hospital is located near a teacher training institution and use can be made of such students from the college. Selected volunteer services from the citizenry are also quite helpful. We found many such persons who were sincerely interested in this type of activity. Daily school sessions are necessarily short, so plans for much supervised recreational and other

activity must be made. Here again students from the college in this special field of recreation and physical education are most helpful. Community facilities, such as: swimming pools, skating rinks, bowling alleys, *etc.*, are readily available at special hours for here again there is a fear of contamination of so-called normal children by contact with these sick children, who are in so many instances craving companionship. For a while we conducted classes for girls and boys separately, but the whole atmosphere improved remarkably when we went to coeducational classrooms. The same was true in connection with recreational activities. There were some problems which developed between the older boys and girls but I understand that is not uncommon in the regular public schools.

The reassignment of facilities in a state mental hospital, to accommodate a part of the needs at least of adolescents and even younger patients with emotional problems will no doubt have to continue at least until the public sentiment becomes sufficiently strong to compel the building of special facilities for this purpose. Where to build separate facilities is still a moot question and there are many good arguments pro and con relative to establishing these on the grounds of already established hospitals. One of the strongest arguments for building them on the grounds of already established hospitals is probably that of utilities, maintenance, upkeep, and food service. There are also

advantages in cases of personnel shortages, as it has been necessary from time to time to draw upon the hospital nursing personnel for assistance.

The hospital administrators are to be commended for their willingness and assistance in developing these facilities in the face of their many other needs. It must be realized that without their sympathetic understanding very little could be done.

The selection of nursing and ward personnel to spend long hours with these children cannot be over-emphasized. There must be a strong empathy with these youngsters and a willingness to vie with them. I mention, for thought, such relationships as always existed with one negro attendant, a college graduate. At any time he was on duty, day or night, everything was serene; all were busy, there was always a feeling of freedom, but at the same time there was a profound respect, and everyone was busy at something, apparently striving to reach a goal. I studied this situation quite a bit as to why and how, but that is a long story.

All of this must, I believe, be under the close guidance of a psychiatrically trained physician who should if possible have no other duties about the hospital. These facilities, where developed and properly organized, can offer a helpful addition to the programs for training physicians and other special personnel, who are interested in the field of child psychiatry.

TEACHING THE INTERPRETIVE PROCESS TO MEDICAL STUDENTS¹

SIDNEY L. WERKMAN, M.D.²

The critical point in the psychiatric diagnostic process is the final interview in which findings and recommendations are discussed. At this time the psychiatrist's understanding of a case is shared, his specific advice in regard to further consultation, placement or treatment is given, and he has an opportunity to assess the probability that his advice will be followed. These aspects of the final interview—the explanatory, elucidative, interactional ones—are what is meant by the interpretive process in this paper. We are not concerned here with the formal psychoanalytic definition of interpretation, that is, the processes involved in making unconscious ideas conscious. The interpretive process is of paramount importance in general medicine, surgery, pediatrics and other specialties as well as in psychiatry, for the success of communication of interpretation, be it recommendation for operation or proscription of certain foods, is necessary for adequate care to follow. Yet the teaching of interpretation is often neglected for a variety of reasons, among them being oversight, an exaggerated belief in the student's capability, a belief in the necessity for each individual to work out his own "style" idiosyncratically, or a recognition of the difficulty of teaching this phase of the "art" of medicine. However, I am sure that it has struck many psychiatrists that the diagnostic process in child psychiatry is particularly suitable for the teaching of interpretation.

Diagnostic evaluations in child psychiatry literally force an awareness of dynamics on the psychiatrist or the medical student who

hears different points of view from parents, the child in the playroom diagnostic interview, teachers and psychologist, and must try to fit these together. A great amount of important material can be amassed from these various sources in a short time and a good view of the longitudinal development of a child can be gained. Further, the student functioning as psychiatrist has the opportunity to share his findings with parents in a way that is sometimes not possible with adult patients. That is, the parents, in fortunate cases, can be called upon to be ancillary colleagues in the treatment of a child's emotional difficulties, a circumstance not often present in work with adults. I will, therefore, use the situation in child psychiatry as illustration for the interpretive process in general, though the primary emphases will be on the way medical students handle the process and on methods of helping them to gain mastery of it. (Many of these observations would seem to be relevant to the practicing physician, but are derived from student experiences because such experiences are available to us and can be studied in detail.) We assume in our teaching that involvement of the student in the actual experience of evaluation of psychiatric problems in children and in the discussion of findings and recommendations with parents is a valuable and economical way of teaching. This assumption is not held in all medical schools as evidenced by reports of various teaching programs(1, 2).

THE INTERPRETIVE PROCESS

This discussion will not dwell on the diagnostic process prior to the time of interpretation. Suffice it to say that by the time the medical student approaches his interpretive interview with a child's parents he has seen one and usually both parents for two or three history interviews, he has observed a skilled psychologist administer appropriate psychological tests, a social worker has supervised his handling of the

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

³ I gratefully acknowledge the collaboration of my colleagues, Sidney Berman, M.D., Erna Bowman, M.S.W., and Sally Segman, Ph.D., in formulating the ideas in this paper.

case, he has had a discussion with a child psychiatrist on the use of the playroom diagnostic session and then has had such a session with the patient, calls have been made to schools, family agencies or other relevant sources of information, he has taken part in a diagnostic conference on the case led by a child psychiatrist, and, finally, he has had a session with a child psychiatrist to clarify issues in the case and prepare him for the interpretive interview, which he will conduct alone or with a student colleague. This general process is reviewed in a previous paper from this department(3). From the many aspects of this process, the one involving psychiatrist and medical student will be examined in detail.

The core problem of interpretation is well stated by the medical student as "How do I tell this mother that her little boy has unmet emotional needs?" It might also be stated as the problem of transforming dynamic concepts into language that can be understood by parents and that is action-directed. It is obvious that this concept of interpretation views it as much more than a statement that "Your child needs psychotherapy." In addition to clarifying dynamic concepts for parents, it is a time for the giving of direct and sometimes painful advice and an opportunity to "sell" the child back to its parents. Also, it is a time for clearly stating the outlines of time, stress and money involvement projected, and a very important opportunity to prepare parents for what they might expect from the child in the ensuing period of work or planning.

All these problems and techniques are worked on in the session with the student that occurs after an entire case has been summarized and its dynamics worked out in a diagnostic conference. A recent GAP report(4) emphasized the importance of this facet of the student's training as follows: "The medical school must train the student for a new social role requiring extensive changes in his attitudes and behavior. He must learn a host of diagnostic and therapeutic skills as well as the technique of entering into a special professional relationship with other persons. . . . Since these situations are often emotionally trying, an important aim of all medical educa-

tion is to help the student become master of the emotions evoked by his dealings with patients. In general terms, the most effective way to bring about changes of this kind is to immerse the student in a new group whose standards represent the attitudes and behaviors he is to learn."

THE STUDENT'S IDENTITY AS A PHYSICIAN

The "set" or environment of the interpretive interview is determined largely by the student's view of his role. The ability of parents to "hear" and profit from the interpretation is dependent upon their acceptance of the doctor's position of integrity and knowledge. This is particularly so since the child psychiatrist has relatively few pills or procedures to offer other than those of thought and action. Thus, even pre-supposing a good knowledge of dynamics on the part of the student, the success of the interview is still dependent on his being able to "get across" to the parents.

Definite problems arise when the student feels inadequate to the role of being a student physician(5). This is not to say that he should have the feeling of an experienced child psychiatrist entering the interpretive interview, but rather that he should see himself as a person with some experience in medicine, who has had the opportunity to study the case in point at some length and with expert help, and who looks forward to the interpretive session as one of learning for himself and of service to the patient and his parents. In addition he should have a comfortable recognition that difficulties might well come up and that he is not expected to have all problems solved prior to the interview. Lacking this identity and a recognition of his importance to the parents, many problems can arise.

When the student's sense of identity is not adequate he is vulnerable to a number of errors in the over-all handling of the interview. Thus, students neglect to introduce themselves to parents, pass over any warmth or pleasantness that can be helpful in starting an interview, and overlook such simple things as using the actual names of the parents instead of "mother" or "father." Such problems as becoming over-familiar,

pompous or "deliberately vague" are sometimes not deeply set characterological ones, but rather the student's picture of what the psychiatrist should be. They are, therefore, susceptible to modification in a useful direction. The basic character organization of the student is important, but also certain elemental lessons in tactfulness, etiquette and warm concern for other people must be inculcated if they have not been so earlier.

Uncertainty on the student's part can accumulate anxiety, and result in his taking a punitive role with the parents, *i.e.* "Your son has trouble in school because you moved twice when he was a little boy and because you didn't spend enough time with him." "How do you expect a boy to grow up well when you started working almost as soon as he was born?" Responses such as these often reflect characterological problems of the students deriving from their relationships with their own parents and are a source of their helplessness. They see problems in the patient and his family, but recognize that these very problems were present in their own lives and were not resolved or were handled by punitive measures only. They then repeat with their patients the very methods they abhorred so much as children, because they know of no other method.

ORGANIZATION OF THE INTERVIEW

Often, the student has no idea how he is going to organize the interpretative interview. Though possessing good knowledge of what should go into the interview, he is at a loss to structure his knowledge. He sometimes rationalizes this by citing the psychiatric therapeutic interview which, to him, is ideally unstructured.

Such students start out interviews with parents by asking them "What do you think is the matter with your son?" or "Do you have any questions?" Such questions after a number of hours of historical material, conference, psychological testing and playroom material are naturally jarring to parents and reflects the student's helplessness. Having almost drowned in opening the interview, the student, if left on his own, often follows up with variations of such gambits as:

Appeal to will power: "That's a problem

that he just has to overcome." (In regard to enuresis.)

Unconscious jealousy and competitiveness: "I don't believe in telling lies to people about their children." (When it was suggested that some of the strengths of a child might be emphasized.)

Pussy-footing: "We've found that there's not much the matter and that your little girl is really in good shape." (In regard to an 8-year-old girl whose problem was school failure.)

Retrospective guilt production: "This happened because you moved so much when he was a little boy, and because he never had a father."

Magical solutions: "He'll grow out of his tantrums if you just don't pay any attention to them."

Punitiveness: "She needs a good going-over by social service." (Said about a mother who was unable to offer warmth to her child.)

Because of these problems it has proved useful to give the student an idea of a reasonable organization of the interpretive session after he has presented his views about it. This is done by introducing role-playing to make the situation as vivid as possible. When confronted with "Here I am; I'm Cassandra's mother; What did you doctors find out about my daughter?" the process that evolves, interspersed with the puzzled questions of the supervisor in the role of mother or father, enables students to recognize how effective they can be. At the same time they are made aware of the boxes into which they can talk themselves.

Role-playing helps them experience the necessity for organizing an interview, the importance of timing of various statements and the potential hurt they can inflict or help they can be. If the students get stuck the supervisor may add a clarifying statement or suggest a way of phrasing a point, thus offering some opportunity for the students to identify with him. During this interactive, role-playing process the following general organization of the interpretive interview is taught the student:

1. His first job is to greet the parents with some warmth and perhaps a casual comment, as peers and dignified human beings.

2. On beginning the interview he reviews the various studies, historical material and tests that have been done. He reviews with the parents what his concept of the presenting problem is.

3. Some positive statement about the child reflecting playroom observation is usually helpful. "Johnny was able to come right in the playroom and get involved in playing with the dart gun, and he had a lot of fun with me. I was impressed with how comfortable he was with a strange person." "I was struck by the interest Johnny shows in things around him, how he is able to make up games in a very imaginative way." It is also useful to recognize how sincere and sharing the parents have been with relatively sensitive aspects of their lives.

4. Interpretation of dynamic material : to be discussed later.

5. Recommendations : They should be clearly in the student's mind, and he should be prepared to give addresses, telephone numbers, *etc.*, for future contacts. If he is referring the child to a boys' club, he should either give the parents the name of the club, or make specific contact for them with a case worker who might follow through on such recommendations.

6. Recommendation of psychotherapy : Students tend either to make a psychotherapy recommendation at the start of the session without preparation for it, thereby incurring hostility or confusion, or they are so apologetic about the recommendation that parents don't understand or accept it. ("And I think that it may be helpful for Johnny to have a little therapy, maybe.") However, in preparation, their experience with the diagnostic process can be reflected on with them as an actual example of the technique of child therapy. With the aid of discussion they are able to formulate with conviction some judgment of the necessary length and nature of psychotherapy and the crucial importance of having parents involved in the treatment of a child. I am convinced that the student's feeling of involvement, and even anxiety, in a playroom diagnostic interview or his investment in interviews with parents are necessary elements in having conviction when interpreting the need for psychotherapy. If students

have had these experiences and have been prepared satisfactorily, they offer a realistic plan for treatment. With this method of preparation we have had a surprisingly high response to recommendations for psychotherapy from parents in a socio-economically depressed, relatively unstable environment.

7. Interpretation of non-psychological findings : When brain damage, physical handicaps or ancillary medical problems are present, students frequently pounce on them and want to deal with them to the exclusion of dynamic problems. For example, there is great relief when an enuretic child is shown to have a small bladder. This appears to remove responsibility from the parents and child and lulls the student into believing that he no longer has to consider problems of dynamic relationships.

Our counter is to anticipate this difficulty, assign a relative weighting to such findings by discussion with the students and, finally, to point out the presence of dynamic problems unsolved by organic findings. A major hazard is the attempt to attribute all problems to an either organic or emotional etiology. Judicious recognition of constitutional variations and, occasionally, a realistic tentativeness in assessing the importance of various etiological factors, seem to permit students to encompass much more of dynamics than does an attempt, usually incorrect, to convince them that "relationship is all."

INTERPRETATION OF DYNAMIC MATERIAL

The playroom interview is a pearl of great price in teaching. It gives fairly spontaneous, direct symbolic material about relationship that, when integrated with other aspects of the diagnostic study, can be told to the parents directly. This is particularly useful for it is not expected that the medical student, and, indeed, the practicing pediatrician will have the background to interpret more subtle interactional dynamics at this time in his training. We might look to a time when much more emphasis on understanding human beings is included in medical school curricula, but at the present time would depend upon "common sense" understanding combined with some knowledge of dynamics. This is

an important distinction, for the medical student who is interested in human beings often dives very deep for the answers to give parents, thereby confusing himself and the parents. It seems more useful to admit the limitations of experience and work at the level at which the student is actually functioning.

Example: The parents of a 7-year-old boy were seen in an interpretive interview after a study in which the presenting problems were tantrums, infantile speech, listlessness and poor school work. In the playroom the youngster was unspontaneous, quite slow in his play, and would not get involved in a pleasurable way with the examiner. His finger was in his mouth and he was quite tense. The parents were baffled, angry and disappointed in their son. Despite the slowness and disdainfulness shown by the youngster, he couldn't help himself from saying quite warmly as they left the room "Can I come back?" The examiner was able to see the wish for relationship on the part of the boy and how fear inhibited him. There were observations from school describing how he cried, needed to have things his own way and was a general nuisance—rather critical statements about the boy. In the playroom session the examiner was able to see that he was also a frightened child. Psychological evaluation revealed considerable immaturity and evidence that the boy saw himself as incomplete, a one-eyed boy, a boy with body parts missing and not able to do things as well as other children. As a result of these insights the examiner was able to reflect his understanding of the boy's tension and feelings of inadequacy and, in a way, to "sell him back" to the parents as a frightened boy who very much wanted to reach out and to be reached out to. He was able to suggest that the father spend more time in playing with him, that the boy be encouraged to play more with other boys and to be directed toward a Cub Scout group. Historically, there was evidence that the youngster had been kept on a bottle until he was four, that he slept in bed with his sisters and that the parents tended to give in to him. It was pointed out that children like to feel a sense of responsibility and are more comfortable when given definite controls by parents. It was suggested that the boy be moved to a separate room from his sisters for sleeping, to emphasize that he was a big boy rather than a baby at this time. While discussing this case prior to interpretation the student said "I don't know what to tell them. How

can I tell them 'You're babying your child too much.'"

He was not certain that he could tell the father that he should spend more time with his son, as the student saw this as a critical statement. He also was helpless with his own feeling that "Answers have to come from within the patient, you can't tell them what to do." This was a problem in confusing deeply internalized compulsive mechanisms and the relatively flexible, malleable character of the child. Considerable discussion of these problems prior to interpretation allowed the student to feel more free and enthusiastic about the interpretive process when he went into it. This particular student had originally planned to point out that "This is a compulsive boy and he can't do anything about it. What he needs is psychotherapy."

The variety of views of such a child is both confusing and clarifying to the student. He is forced to think in a number of different ways about a single case. That is, the boy who is "mean" and gets into fights, shows himself to be a frightened, immature youngster in the playroom, crying for a bottle and still fighting the developmental battles of infancy. The student can then understand the meaning of "infantilization" on the part of the mother. The playroom interview gives him material to interpret to the parents in a most vivid way. He has actually related to the youngster and has a feeling for the problems faced by the patient and his methods of dealing with them.

THE USE OF ADVICE

Students often hesitate to give direct advice to parents. This hesitation stems, in part, from their image of the psychiatrist as a non-directive person and from the recall of their own helplessness in handling problems similar to those of their patients. ("How can I tell them to change when I was afraid of the dark when I was eleven?") However, of equal significance and with more possibility of change, is the lack of a definite conception of what constitutes good child development practice.

The importance of regularity, firmness and consistency in setting controls, and

the handling of usual developmental crises such as the birth of siblings, night fears, school problems or transient enuresis are seemingly not encompassed in any systematic view by many students. It is refreshing to work with the occasional student who has definite common sense ideas about such problems and who comfortably advises about them even without a thorough knowledge of psychodynamics. It is possible that much of the non-specific reassurance given to parents is not a function of character problems in students but rather of a simple lack of knowledge of how to handle specific situations.

CONCLUSION

We are by no means finished in our exploration of better ways to teach the interpretive process, and it is obvious that many other factors not covered here are involved in the process. Certainly a great deal of psychiatric learning occurs before this experience just as a music student masters volumes of scales and technical exercises before he is able to enjoy working on a concerto. The interpretive process in psychiatry is a concerto with specific technical, organizational, dynamic and stylistic demands. In the teaching of this process, questions about child development can be clarified, distinctions between diagnostic interpretation and psychotherapy are made, problems concerning the weighting of organic disorders can be examined, some prejudices about psychiatry can be melted

and the student's identity as a physician can be strengthened.

Student response to this method of teaching is of interest. Following the actual interpretation interview, we discuss their impressions with the students. Here are several of them: "We were just slugging it out with her. I didn't know where I was going part of the time. The main thing, though, is until now I didn't see how we could do anything, and now I think we've really helped her." Another: "When I found out I had to come over here, I thought, 'Oh, God, listen to somebody else's troubles.' But this was different. This brought everything together. I never knew what psychiatry was before this."

The enthusiasm and involvement of students in this program suggest that it is valuable to focus on teaching this phase of psychiatry. This paper has been an attempt to detail one method of doing so and to discuss issues that arise in the course of this teaching process.

PSYCHOTHERAPY AS A SYSTEM OF ACTION¹

HELEN C. HENDIN, M.D., HENRY L. LENNARD, Ph.D., AND
ARNOLD BERNSTEIN, Ph.D.²

In this paper we shall discuss some issues raised by a four-year study in which techniques and concepts from the sociological theory of small groups were applied to the psychotherapy situation in the hope of furthering our understanding of this relationship.

A study of the social system aspects of the psychotherapy relationship is somewhat analogous to a study of the grammar of the English language. Just as one may be unaware of the syntax and grammar underlying his communication, so may therapist and patient be unaware of certain regularities underlying their interaction(1).

The challenge of such an inter-disciplinary effort has been well formulated by a philosopher of science(2) :

... of all forms of mental activity, the most difficult to induce is the art of handling the same bundle of data as before, but placing them in a new system of relations with one another, by giving them a different framework.

While the main findings of the study have been reported in detail elsewhere(3) this paper concerns itself mainly with some of the questions raised for the psychiatric clinician.

What is meant by "applying sociological concepts and methods to the study of psychotherapy?" What purpose does such a study serve? Two major points of departure are involved. In terms of *methodology* we assume the position of an outside observer while in terms of *theory* we view the psychotherapy relationship as a social interaction system.

What is to be gained by assuming the vantage point of the outside observer? First of all, he is not limited by the theoretical postulates of the participants. He is in a position, not enjoyed by them, to review the same body of data repeatedly, to ana-

lyze the same communicative acts from as many points of view as his imagination will permit, and to arrange and cross-tabulate the material in a variety of sequences and patterns.

Taking the position of such an observer enabled us to quantify a number of different dimensions of communications and expectation and has shown the feasibility of creating a research approach that can be adapted by other workers to study dimensions of therapeutic communication of interest to them.

In such work, of course, to quote Bales, "one must give up the pleasure of believing that one can understand everything at once from the grand vantage point of the eagle and accept instead the plodding way of the burro"(4).

Now, what about the concept of system in relation to psychotherapy. When two or more people interact, the sociologist finds it useful to consider them to comprise a system. This concept has been applied and studied in diverse social contexts, such as the family, problem solving groups, work groups.

Social systems like other systems are postulated to possess certain common characteristics (system processes and properties). Among these are :

Interdependence—the existence of determinate relationships among the parts or variables, or, in other words, the units of the system are related to each other in an orderly fashion.

Equilibrium—the order exhibits a tendency toward self-maintenance: it need not, however, be a static self-maintenance. It may be helpful to think of a social system as "an accounting system which takes account of deficits and surpluses that appear ... in such a way as to tend toward restoration of certain balances"(5).

Differentiation—Differentiation is defined as a temporal or phase phenomenon in which the behaviour of the participants is seen to change over time in an orderly

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Columbia University, New York, N. Y.

fashion. There are regular increases and decreases in the frequency of certain forms of behaviour.

Viewing therapy in this light implies that in addition to individual psychodynamic processes, one must take account of behaviour as determined by system processes and properties.

These system processes appear to lie outside of the awareness of the participants. With regard to the psychotherapy situation, this seems to be due to, among other reasons, the clinician's lack of familiarity with social science concepts; his necessary commitment to psychodynamic content and meaning of patients' communication; and to the temporal characteristic of such processes, that is, they occur too slowly or too quickly to be kept track of consciously.

The significance for the clinician of our emphasis on system may be put this way: What is latent for the personality are "unconscious" processes while what is latent for the social system are system processes. By making an individual conscious of hitherto unconscious processes, one increases his adaptive control and flexibility. The identification of system processes can serve a similar function for the therapist. By enlarging the therapists' awareness of all processes taking place in the therapy system, one may make possible an increased measure of responsiveness and control on his part(3).

What was the procedure used in the study, what were the findings, and what are some of the issues raised by these findings?

PROCEDURE

Five hundred psychotherapy sessions (2 patients each for 4 therapists), for an 8-month period, were recorded, and each verbal statement made by either therapist or patient in a sample of 120 sessions were classified, coded along multiple dimensions, and punched into IBM cards and machine processed. More than 40,000 verbal communications of therapist and patient were classified in terms of: Quantity of verbal output, Informational Specificity, Affective Content, Interaction Process Categories, and Role System Categories (Table 1).

TABLE 1

CATEGORIES USED IN DATA ANALYSIS

Units of Quantity :

- (1) Proposition
- (2) Statement
- (3) Exchange

Categories of Informational Specificity :

- (1) Passive encouragement
- (2) Active encouragement
- (3) Limits to subject matter area
- (4) Limits to specific old proposition
- (5) Introduces specific new proposition
- (6) Interpretation
- (7) Limits to specific answer
- (8) Excludes discussion

Grammatical Form of Propositions :

- (1) Declarative
- (2) Imperative
- (3) Interrogatory

Affective Content of Propositions :

- (1) Expresses or refers to feelings, affective
- (2) Does not refer to feelings, non-affective
- (3) Affective content indeterminable

Interaction Process Categories :

- (1) Descriptive
- (2) Evaluative
- (3) Prescriptive

Role System Reference Categories :

- (1) Primary System Information
- (2) Secondary System
- (3) Tertiary System
- (4) The Self

Although the 4 therapists participating in the study consider themselves as working within a psychoanalytic framework, they differed considerably in type of training, theoretical dynamic orientation, and concepts of technique and personal characteristics. The patients in the sample were referred to therapists on a random basis.

FINDINGS AND IMPLICATIONS

A. Among the most striking findings was that, despite differences in therapist and patient, there were *major similarities* in terms of the way the interaction process unfolded longitudinally. We shall discuss some of these similarities which appear to be of particular interest.

1. We found a decrease over the first 50 sessions of therapy in what we call primary system communications (included in this category are patient and therapist propositions that refer directly to their roles dur-

ing treatment, the process of therapy and to the purposes and goals of therapy). It should be noted that this category does not refer to communication about transference behaviour (Figure 1).

Illustration of Primary System Communication Patient :

I'd like to talk about this but don't suppose it's important.

Therapist : Talk about it anyway even though you think it's unimportant.

Similarly, therapist communications classified as providing orientation (giving of clarification, confirmation) decrease over the first sessions of therapy for all 8 therapists.

The decrease in communication about the primary role system occurs for our study group as a whole and appears as a trend in every one of the 8 therapist-patient pairs. This decrease in primary system communi-

cation as well as the decrease in therapist orientation communication reflects the inevitability of socialization as a consequence of psychotherapy, irrespective of the ideology and skill of the therapist and the psychological problem of the patient. To resolve the problem of what a patient may expect in his role as a patient and what may be expected of him in this role appears to be a requisite for the maintaining of the therapy system.

2. We also found an increase in communications dealing with affect (included in this category are therapist and patient statements referring to feelings).

Illustration of Affective Communication

Patient : I felt very angry.

Therapist : You felt sad?

As therapy proceeded, the therapists increased the frequency with which they inquired into and solicited patient verbaliza-

FIGURE 1

PATTERNS OF TEMPORAL DIFFERENTIATION OVER 50 SESSIONS OF THERAPY :
THERAPIST AND PATIENT PRIMARY SYSTEM PROPOSITIONS

Sub-periods within the first 50 sessions are : (1) sessions 1-3 ; (2) sessions 4-6 ; (3) sessions 7-8 ; (4) sessions from the third and fourth months of therapy ; and (5) sessions from the fourth through the seventh months of therapy.

n = 101 sessions or 9,282 therapist propositions and 32,231 patient propositions.

tions about feelings and also, patients began to verbalize more about feelings (Figure 2).

The inverse movement of primary system communications and affective communication over time is *not incidental* to but derives from the very nature of the therapeutic task. Precisely, one of the things the patient learns about his role as a patient is to put his thoughts and especially his feelings into words. The freeing of affect is one of the goals of the therapy.

3. We found increasing similarity of patient and therapist behaviour over time with respect to 3 dimensions of communication, *i.e.*, primary system communications, evaluative communication and affective communication. We are using the term "similarity" to refer to the increasing *correlation* over time between specific kinds of patient and therapist communications. For example, while the correlation between percentage of therapist and patient affective propositions is .23 for the first two sessions, this correlation increases to .70 by the third and fourth month of psychotherapy.

This latter finding raises an interesting question. The data show that during therapy there is a growing similarity in verbal behaviour between therapist and patient, *i.e.*, they become more alike in terms of the categories of verbal expression they employ to describe their thoughts, feelings, and action. The theoretical implications this

finding raises is whether a growing similarity in the verbal formulation of experience *also implies* a growing similarity in more lasting and deeper aspects, such as: patient perception of experience and patient value system.

The problem of defining the extent of the therapist's influence upon the patient is an important and complex one. While the clinician has always suspected that he exerts some measure of influence on his patient's perception of the world, his attitudes and values, direct documentation of this process has been lacking. Our research supplies some information of how this occurs, but leaves many problems still unresolved. Further work, then, on specifying the relationship between perceptions and values, on the one hand, and verbal articulation of feelings and thoughts, on the other, is required.

What are the implications of such evident similarities in the behaviour of different therapist-patient pairs for our understanding of the therapeutic process? So far, clinicians have been mainly concerned with the effectiveness of different psychodynamic frames of reference in achieving therapeutic results. Since the research revealed large areas of similarity in the unfolding of therapist-patient interaction, we are now raising the question as to what "therapeutic" goals may be served by behavioural processes occurring *consistently* in the therapist-patient pairs studied.

FIGURE 2

* PATTERNS OF TEMPORAL DIFFERENTIATION OVER 50 SESSIONS OF THERAPY :
THERAPIST AND PATIENT AFFECTIVE PROPOSITIONS

n = 101 sessions or 9,282 therapist propositions and 32,231 patient propositions.

* See Fig. 1 for specification of the 5 sub-periods.

We shall not discuss factors ordinarily mentioned in connection with the similarity issue, such as catharsis, the therapist as sympathetic listener and friend, *etc.* We are specifically concerned with the therapeutic implications of the kinds of similarities found in *our* data.

These appear to grow partly out of the uniform requirements for patients in psychotherapy to articulate their feelings and thoughts. We believe that Sullivan's statement to the effect that "one has information about one's experiences only to the extent that one has tended to communicate it to another" contains a measure of truth(6).

"Not only do patients learn to articulate feelings and thoughts in words, but also they learn to express them increasingly in particular language categories such as evaluative and affective communication. During the first 6 sessions the therapist employs a higher proportion of statements dealing with affect than the patient. Both therapist and patient increase their communications dealing with affect in the course of therapy, but the therapist consistently stays somewhat ahead in his usage of this kind of communication.

One consequence of this increase in affective communication for the patient might be to concretize and put him in touch with his feelings, so that he can achieve more harmony between feelings and behaviour. A therapeutic consequence of the patient's learning to employ evaluative statements in his description of self and inter-personal relationships may be to provide him with a sense of explanation and control.

The implication of similarity in occurrence of patient role learning during therapy, as evidenced by consistent decreases in pri-

mary system discussion for all therapist-patient pairs, appears to be the following:

The patient learns that adequate functioning in the patient role requires him and the therapist to discuss their mutual expectations and obligations. This frame of reference applied to his relationships outside of therapy enables the patient to perceive more clearly one aspect of interpersonal strain, *i.e.*, expectational disequilibrium (for example, he becomes aware of non-fulfillment of expectations in his marital relationship as one source of difficulty).

B. A second set of consistent findings of interest, deal with system strain in therapy and tendencies toward reestablishing of system equilibrium.

1. We found that disequilibrium or strain occurring within *one* session affected the structure of communication occurring within the subsequent session. For example, we considered a large number of silences in a session to reflect communicational strain. Sessions with the most silences were followed by sessions with a higher percentage of therapist evaluative and informationally specific statements. That means that therapists become more active, concrete, and interpretative in sessions following high silence sessions (Table 2).

2. Within the span of a single session, too, there occur self-adjusting processes which serve to preserve the continued flow of communication. We found a systematic relationship between therapist and patient output for given time spans. Low structured therapist behaviour, that is, non-specific remarks on the part of the therapist (such as "well" or "go ahead" or "tell me about this experience"), in general tend to be followed by a high patient output (lengthy

TABLE 2

High	.19	.52	.38	.24	.19	.25	.34	.29	
Low	.18	.40	.28	.09	.14	.12	.31	.22	

n = 64 sessions.

patient verbalizations). Highly structured therapist behaviour, on the other hand (for instance, specific questions), tend to be followed by medium patient output (defined as more limited verbalization). When communication breaks down, however, as indicated by low verbal patient output or patient silences, then highly structured therapist statements follow. Apparently, then, special measures are needed to get communication moving again. In other words, therapists feed more information into the system when patient output falls and less information into the system when patient output is high.

3. Utilizing our questionnaire data we found that communication in sessions in which therapists were more active was rated as more satisfactory than sessions in which therapists were less active. Therapist activity was defined in terms of quantitative as well as qualitative aspects of communication. Active therapists talked more, more often, made proportionately more affective and informationally specific statements.

During sessions in which therapists are less active, patients expressed more dissatisfaction with the therapy interaction. Patients of the two therapists who consistently were less active broke a greater number of appointments than did the patients of the two more active therapists.

Thus, lack of therapists' activity was found to be related to heightened system strain as reflected in expressions of frustration and dissatisfaction both within the session as well as in patient ratings of particular sessions on questionnaires.

The lack of satisfaction with sessions in which therapists are less active is accounted for by the fact that during those sessions, patients' expectations and hopes are disappointed. Verbal output on the part of the therapist may be interpreted as a "gift from the therapist." Therapist activity and lack of participation may be equated by the patient with rejection, abandonment, and reacted to with frustration. When therapist and patient expectational discrepancy is too great, therapy—as we found—may be terminated.

What are some issues of clinical interest

arising out of these findings about system strain and regulating processes?

We find evidence that the greater the system strain, *i.e.*, divergence in expectation and patient frustration, the more is dissatisfaction overtly felt by the patient; if the strain increases beyond a certain point, the system is interrupted, *i.e.*, the patient quits treatment.

The question is, what is the relation, if any, between system strain, or inversely, the maintenance of smooth flow of communication in therapy and accomplishment of *therapeutic goals*. This is most complex. Maintaining the system, *i.e.*, doing what is good for the system, is not necessarily synonymous with fulfilling the therapeutic task, *i.e.*, doing what is good for the patient. There is considerable evidence for the view that the differences in patient and therapist expectations are used by therapists to advance treatment. In his reaction to the frustration, patient's motivational processes are revealed and his emotions are expressed. These differences become the very subject matter of analytic interpretation. Eliminating "strain" from therapy would be eliminating an essential element of treatment. Giving in to patients' transference expectations, would mean giving up of the therapeutic task. In other words, the system might be restored at the expense of therapeutic goals. It is well known that patient's overt satisfaction with an hour is not always synonymous with an evaluation of the therapeutic effectiveness of that hour. On the other hand, excessive strain, frustrations, a lack of taking account of patient expectations can be harmful to therapeutic goals. The reaction stirred up in the patient may be so overwhelming that he is unable to deal with them and communication is unnecessarily and increasingly interfered with. If the expectations are too divergent, *i.e.*, the system strain is too great, the system is interrupted, *i.e.*, therapy is discontinued by the patient. Obviously, the therapist can be of no help to the patient if this happens since therapy cannot be conducted without the patient's presence. However, this does not mean an indication that the system must be maintained at all costs. Some people could be and, perhaps, are kept in therapy, *i.e.*, the system maintained by acceding to pa-

tient's self-damaging demands, at the cost of some or all therapeutic goals. This would be of little help to the patient, but may provide him with a false sense of accomplishment.

Therapeutically useful system strain is a delicate balance between the demands of system maintenance, patient satisfaction, and optimal quantity of patient frustration. Too much sensitivity to system strain on the part of the therapist might endanger important therapeutic goals, while too little interferes with the development of a potentially useful therapist-patient relationship.

CLINICAL PROFILES OF PAID NORMAL SUBJECTS VOLUNTEERING FOR HALLUCINOGEN DRUG STUDIES¹

HAROLD ESECOVER, M.D., SIDNEY MALITZ, M.D., AND
BERNARD WILKENS, M.D.²

The role of the "normal control" volunteer in current psychiatric research is a crucial one. Many basic psychopharmacological problems have been explored by means of the study of volunteer subjects. The assumption implicit in these studies has been that the volunteers were "healthy." The results with these groups were then compared with the "sick" groups and conclusions drawn on the basis of the differences between them. But an individual's decision to volunteer for a research study may be indicative of personality deviation or psychopathology in varying degrees. This can result in psychologically unrepresentative samples, and conclusions based on such studies applied to the general population must be carefully evaluated. Lasagna and von Felsinger(2), on the basis of psychological tests given to a group of student volunteers participating in drug response studies documented a higher incidence of psychopathology than might be expected in a randomized selection of an undergraduate population. Pollin and Perlin(7), in a clinical study at the National Institute of Mental Health, demonstrated a high incidence of "significant psychopathology" in volunteers. Brower(1), Maslow(3), Maslow and Sakoda(4) and Riggs and Kaess(6), using a wide range of psychologic and psychomotor techniques claimed significant differences between volunteer and non-volunteer groups.

Our study dealt with clinical psychiatric evaluations of 56 subjects volunteering for hallucinogen studies at the New York State Psychiatric Institute from 1956 to 1959. Our focus in this work was on motivations for volunteering, incidence and types of psy-

chopathology, relationship between psychopathology and motivations, and personality patterns.

MATERIAL AND METHOD

The sample was composed of 46 males and 10 females ranging in age from 21 to 38 with a median age of 23.4, with varying occupations but a high preponderance of students (Figure 1). All subjects had some

through recommendations of their friends who had participated in a study.

All volunteers received an initial 1 hour psychiatric screening interview. The interview was a semi-structured one, with suf-

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1966.

ficient latitude given so that spontaneous material could emerge. Specific areas such as personal and family history, motivation, over-all life adaptation and symptoms were covered. Subjects who demonstrated acute neurotic or psychotic symptomatology were excluded from the hallucinogen study. Those accepted received oral doses of LSD-25 or one of its derivatives, psilocybin or placebo. They were paid \$25 for participation in the study. Each subject received from 1 to 3 follow-up interviews lasting approximately 45 minutes on separate days beginning 24 hours after the study. These interviews focused mainly on subjective reactions to the drug experience, but in certain instances pertinent psychodynamic factors became apparent. This was true particularly in instances where the drug had stimulated the uncovering of repressed material or where post-drug reactions of anxiety, depression or somatic reactions had developed.

Forty of the original 56 volunteers received 30 to 60 minute follow-up interviews from 6 months to 4 years after the initial screening interview. An attempt was made to contact all the original volunteers. Some had moved out of town, others had moved and left no forwarding address. An additional fee of \$5 was offered as incentive to return for the follow-up interview. Further material was obtained about life adaptation from these follow-ups since the study, and motivation for volunteering was reviewed retrospectively over an extended time interval. Data from all interviews were then independently evaluated by the initial interviewer and 2 other psychiatrists. Two of the raters were Board certified psychiatrists, the third was Board eligible. In addition, one of the 3 was a graduate of an analytic institute and the other 2 were in analytic training. Clinical psychiatric diagnoses were made where indicated and personality patterns were delineated. In addition, each volunteer was evaluated as to whether or not in the opinion of each therapist, he needed psychiatric treatment.

RESULTS

A. Motivations: Motivations for volunteering were frequently quite complex and could be seen as operating simultaneously

on 2 levels. Consciously stated motivations on one level; pre-conscious and unconscious ones on another. In only certain instances did we feel that we could determine the pre-conscious and unconscious roots. We felt that the subjects' conscious motivations could generally be broken down into the following broad categories: 1. Financial need; 2. Scientific interest and curiosity; 3. Seeking new experiences (adventure); 4. Indirect seeking of psychiatric help; 5. Symptomatic relief from tension, depression or anhedonia; 6. Searching for insights into personal problems; 7. Desires for status or prestige; 8. Employing the study as a vehicle for the expression of socially unacceptable impulses; and 9. Hope of stimulating creativity through drug induced perceptions. The following brief examples will serve to illustrate some of these categories:

1. *Seeking relief from anhedonia:* A 21-year-old single male undergraduate volunteer majoring in physics described obsessive fears of dying and of pointed instruments piercing his eyes. He was undergoing a classical analysis 5 times a week at the time of volunteering. He openly expressed his feelings of boredom and anhedonia as follows: "I'm bored by nearly everything in life. I'm looking for new forms of excitement. The only reason I don't take heroin is that it's addicting. One of the happiest days of my life was the day I took mescaline." This subject was not accepted for drug studies. He revealed in a follow-up interview that he had begun to take mescaline regularly. It seems clear that he consciously sought relief from anhedonia through means of the anticipated "pharmacogenic pleasure effect" (5) of the drug.

2. *Seeking relief from tension:* A 20-year-old single male with symptoms of chronic tension, potency difficulties, alcoholism and bronchial asthma had participated as a volunteer in our studies on 5 separate occasions. He revealed that as a result of the first study he had become aware of "all the pressure I put on myself. I felt while under the drug as if a great weight had been lifted from my shoulders. I felt for the first time really at peace with the world." His repeated acts of volunteering seemed to be in part conscious attempts to reproduce the symptomatic relief he had both anticipated and experienced during his initial contact with the drug.

3. *Indirect seeking of psychiatric help:* A 22-year-old married female with highly com-

petitive strivings toward masculine figures volunteered for the study with the consciously stated motivation of "being interested only in the money." She had a good deal of suppressed and repressed rage toward female authority figures stemming dynamically from an unresolved conflict with a controlling, domineering mother. She developed a post-drug reaction of mild depression, anxiety, and irritability, with obsessive angry ruminations about her mother-in-law. She was seen by one of us for 5 psychotherapeutic sessions, and during the third session spontaneously stated that she was able to recognize that in volunteering she had been looking for some psychiatric help to aid her in solving her marital problems. As a result of the drug experience she felt that she "got not only what I was looking for, but much more than I bargained for." The subject was referred for private treatment and is now receiving psychotherapy.

4. *Seeking new experiences (adventure)*: A 38-year-old schizoid bachelor poignantly expressed his feelings of disappointment in his search to alleviate the isolation of his daily living as follows: "I somehow feel that I missed out on many things in my life. I was never in the service because of my deafness and I've tried to make up for this by traveling. But I've felt a further need for such experiences and the drug seemed to be able to supply this to me."

5. *Desires for status and prestige*: A 27-year-old oriental student married to a white woman had sought for identification with whites throughout his life. He attempted to deny his own racial origins and tended to think of himself as white. He felt that he had gained prestige through participating in the study because "very few people have gone through this and I am in good company—people like Aldous Huxley." Huxley was much admired by this subject.

6. *Employing the study as a vehicle for the expression of socially unacceptable impulses*: A 23-year-old obsessive, over-controlled student with symptoms of sexual inhibition and recurrent gastrointestinal complaints retrospectively stated his expectancy of the study as follows: "I felt that for me the study might be an uninhibited experience where I could let myself go and express myself in an emotional way; maybe grab one of the nurses. You know how rationally I approach everything." It seems evident that the drug experience represented a solution to problems of neurotic inhibition. The subject anticipated the drug effects and the milieu of the study as a situation in which he might loosen controls and act out sexual impulses in a permissive non-punitive setting.

An example of pre-conscious and unconscious determinants can be illustrated by the following:

A 23-year-old male art student had entered psychotherapy because of phobic and obsessive symptoms, under coercion from his parents. He showed a characteristic pattern of defiant, provocative and self-destructive acting out toward male authority figures. This related to unresolved conflict with a perfectionistic, demanding father who insisted on superior academic achievement. The subject had consulted his therapist prior to volunteering, but had been discouraged by him from participating. A power struggle then ensued over this issue. When the patient insisted on going through with the study his therapist attempted to prohibit this activity by threatening to discontinue therapy. In the face of the patient's adamant refusal to accept this limitation, the therapist capitulated, in order to prevent a complete breakdown of therapy. By using volunteering as a means of acting out, this subject was unconsciously attempting to defy authority in a transference repetition of an earlier childhood behavior pattern.

B. *Psychopathology*: Diagnoses were made on 26 subjects. Twenty-three of these 26 subjects were evaluated as "needing psychiatric treatment" (Figure 3). The degree

chiatric treatment. Twelve subjects either had a history of previous treatment, were in treatment, or entered treatment after volunteering (Figure 6). The occurrence of symptoms was tabulated for each volunteer (Figure 7).

C. Relationship between Motivation and Psychopathology: The group of subjects with better life adaptations were motivated mainly by financial need, scientific interest and curiosity, or combinations of these. Subjects with significant psychopathology tended frequently to volunteer for reasons related to maladaptive patterns. They often perceived drug effect and the milieu of the study as having a problem solving function. Some saw the study as a means of making contact with psychiatrists; others as fulfilling frustrated needs for excitement and adventure. Those with symptoms of anxiety, depression or anhedonia sought magical relief from these painful feelings. Some subjects hoped to undergo transcendental experiences. Inhibited, repressed subjects fantasied being able to act out forbidden impulses. Subjects with high addictive

potentials looked forward to the "pharmacogenic pleasure effect" (5) of the drug. Several of these subjects reported using mescaline regularly and deriving from it incomparable feelings of excitement and enjoyment.

D. Personality Patterns: Personality patterns covered a wide range which included hysterical, obsessional and schizoid types. The latter 2 categories predominated. A variety of adaptive defenses were utilized by different individuals in coping with drug-induced stress. In addition, there was considerable variation in the degree of ego disorganization induced by the drug. A study is now in progress attempting to correlate the total behavioral response pattern to hallucinogens with personality variables.

DISCUSSION

Although diagnostic categories are admittedly rough estimations of psychopathology they can be exceedingly useful. On the basis of our clinical impressions the prevalence of psychopathology in the volunteer group seemed quite high. Psychiatric diagnoses were made on almost 50% of the group. More than one third of the group

were rated as "needing psychiatric treatment," and one fifth of the group were or had been in psychiatric treatment. These results are similar to the incidence of psychopathology reported in Lasagna's study (48%) and in Pollin and Perlin's work (52%). Our findings re-emphasize the need for detailed psychological study and careful screening of volunteers for psychiatric research. In some instances psychopathology not uncovered in the initial screening interviews, was revealed in follow-up. Subjects tended to be less guarded and more revealing of emotional difficulties in follow-up interviews. Removal of the competitive pressure for selection may have made some subjects less reluctant to expose themselves. In some instances we observed the development of a strong positive transference towards the experimenter as a result of his close contact with the subject during the stressful hallucinogen experience. This also may have facilitated the elucidation of further data in the follow-up interviews. In addition, the extended time span between the initial and follow-up interview, in some instances up to 4 years, permitted us to scrutinize a broad segment of the subject's life adaptation. In several instances we learned of subsequent decompensation and the initiation of psychiatric treatment. All of these factors underscore the methodological value of follow-up interviews in such a study.

Our volunteer sample was homogenous only in respect to the uniformly high social, cultural and educational level of the group. In terms of psychopathology and motivation 2 sub-groups can be differentiated. One group was composed of subjects with healthy life adaptations motivated primarily by financial and scientific reasons. The second was made up of individuals with varying degrees and types of psychopathology motivated by reasons frequently related to their psychopathology. Within these sub-groups there existed considerable differences in personality structure, defense mechanisms and means of adapting to stress.

Pollin and Perlin(7) found in their series, that the greater the social stimulus to volunteer, the less was the degree of psychopathology present. Our results confirm this find-

ing. Medical students live in a milieu which encourages volunteering for scientific studies. Over 2/3 of our medical student volunteers were classified in the group with the most successful life adaptations. On the other hand, only 1/4 of our volunteers in all other occupations were placed in this category while 3/4 were classified in the group with psychiatric diagnoses. This difference is statistically significant beyond the .01 level of confidence.

Popular literature on hallucinogens is replete with references to mystical sensations experienced in an atmosphere of splendid isolation. These romanticized accounts may have attracted the large number of schizoid individuals identified in our sample. Tending to handle life situations in an introspective autistic manner, these subjects may have expected sensations which as one volunteer commented, "would take me out of this world."

The high incidence of obsessional traits may bear a direct relationship to the large proportion of medical students in the sample. It is known that professional men such as lawyers, doctors and engineers number a high percentage of obsessional character types among their ranks. Since medical students are in professional training, they have similar character traits and this fact may have weighted our sample heavily in that direction.

The surprising high degree of concordance in the diagnoses and evaluation of need for treatment among the 3 psychiatrist raters may be explained on the basis of 2 factors. One was the similarity of their psychiatric training and experience; the second was a tendency to share similar viewpoints and attitudes toward diagnosis and treatment based on working closely together over a period of several years.

SUMMARY

1. Psychiatric evaluations were made of 56 volunteers for hallucinogen studies. Diagnoses were made on 46% of the group. Forty-one percent were estimated as needing psychiatric treatment. Twenty percent of these had received some form of psychiatric treatment.

2. Those subjects with the more effective life adaptations were motivated to volun-

teer mainly for financial and scientific reasons. Those with diagnosed psychopathology tended to volunteer for other reasons frequently related to their maladaptive patterns.

3. The greater the social stimulus to volunteer, the less was the degree of psychopathology present.

4. Follow-up interviews frequently revealed psychopathology not ascertained in initial screening interviews. The removal of competitive pressure for selection, the development of positive transferences to the investigators through the hallucinogen experience and the broad time span covered by the follow-ups might explain this.

5. Personality patterns covered a wide range with obsessional and schizoid types predominating.

6. There was a high degree of agreement among the 3 rating psychiatrists regarding

diagnosis and need for treatment. The raters had similar training and experience. They had worked closely together for several years, developing a similar "philosophy" of psychiatry. These factors may have contributed to the high concordance.

NEW INTERDISCIPLINARY TRENDS IN PSYCHIATRY¹

CHARLES E. GOSHEN, M.D.²

One of the most fashionable, most discussed subjects in the total field of science today is that of the "interdisciplinary approach." By this is meant the joint application of more than one type of scientific thinking to the solution of a common problem. Partly, this trend is a revolt against the tendency in recent years for the various scientific disciplines to have become excessively narrow and specialized. Partly, also, it is a recognition of the greater complexity of today's scientific problems. Above all, it reflects a healthy interest in finding ways to solve the "whole" or "total" problems of mankind in contrast to the more traditional interest of science in studying the "parts" or "fragments" of human problems.

Psychiatry has a very unique role in this new trend, having led the way in introducing the concept of the interdisciplinary approach. It was first developed during World War II when military psychiatry evolved the concept of the "team," made up of a number of different disciplines as a way of meeting a tremendous demand for psychiatric services in the face of very limited manpower resources. Perhaps even more important, though, is the fact that the study of psychiatry stands in a very strategic position in the total field of science by virtue of having one foot planted firmly in the biological sciences, and the other in the social or, behavioral sciences. Perhaps no other discipline is presented with such unique opportunities as is psychiatry in bringing about a comprehensive understanding of man from a knowledge of both man's biology and his humanity. Nearly all other fields of science specialize in one or the other aspect of human existence, but psychiatry is in a position to study and understand both of them together. For this reason, it is most urgently recommended that psychiatry assume a dynamic leadership in the further development and refinement of the "interdisciplinary" concept. In

particular, it would be appropriate for psychiatry to assume the initiative in the fields of medical education, in scientific research, and in social planning wherein it is expedient that proper recognition be given to both the biological and the human side of man.

In addition to psychiatry's fairly long experience in dealing with the problems associated with the interdisciplinary treatment of patients, involving the joint efforts of psychiatrists, social workers and psychologists, a new type of problem is now developing in relation to other disciplines. In this area, psychiatry has not been the one to lead the way, and it is possible that we might suffer as a consequence. The following is an attempt to highlight some of the ways in which psychiatry has failed, perhaps, to make its message clear, a default which is helping other disciplines to build up erroneous programs based on incorrect assumptions. It would seem to be the responsibility of psychiatry to correct these misconceptions.

PUBLIC HEALTH AND MENTAL HEALTH

The new type of "interdisciplinary" approach referred to is the one in which public health people, particularly, have recently come to take an interest. It is sometimes termed the "epidemiological study of mental illness." Those who make these studies tend to take at face value the data produced by some of us psychiatrists, and may not be aware of some of the important contradictions inherent in them. The public health professions are increasingly aware that psychiatric disabilities constitute one of our largest public health problems today, an awareness which we must encourage. Unfortunately, however, the traditional methods of doing epidemiological studies are not as applicable in the same literal way to mental health as they are to the study of such conditions as typhoid or TB, for example.

To begin with we suggest that the term "mental illness," itself, is merely an euphemism. The application of the term "illness"

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² The Washington Clinic, Washington, D. C.

to psychiatric problems has come about mostly because the study of these problems has come under the province of medicine, and not because there exists a state of "illness" which is comparable to the pathological states seen elsewhere in medicine. The institutions in which people with psychiatric problems are cared for have recently come to be known as "hospitals" chiefly because physicians work in them and usually exercise administrative control over them, and not because they have been designed to offer a unique clinical service. These euphemisms are characteristic of physicians, and it is safe to predict that when administrative control of any institution falls into the hands of physicians, it will become known as a "hospital," and the people who are being serviced will become known as "patients." For example, institutions for the mentally retarded are changed from "schools" to "hospitals" by the simple process of changing the administration from one professional field to another. The individuals who are cared for in "mental hospitals" are not segregated from society by virtue of their having an "illness," although this is the common assumption, but, instead, it is because of the fact that they have exhibited a type of behavior which society finds unacceptable.

The conditions which are commonly classified under the category of "mental illness" are frequently subjected to statistical investigation by public health people. In doing so, they tend to assume that they are dealing with phenomena comparable to typhoid or malaria, and apply similar statistical methods to their studies. Because these assumptions are incorrect, there is a growing number of misleading reports coming out under the general category of "epidemiology of mental illness." A case in point is a recent publication of the Senate Subcommittee on Reorganization and Internal Organization on the subject of "Patterns of Incidence of Certain Diseases Throughout the World." The citing of this publication is important because its data are likely to provide the background material for the establishment of an "International Health Institute," and any errors in it may become expressed in the form of legislation which could easily lead to a

considerable waste of money and manpower.

Under the section entitled "Mental Illness," this publication draws appropriate attention to the international scope of the problem of psychiatric disorder, and the conventional plea is made that "There is great need for research on an international level in the field of mental illness and mental health." It is mentioned that there exists a state of "unsatisfactory knowledge regarding the etiology and epidemiology of mental disorders" (which is not true in the sense in which it was intended), and reference is made to the logical source of data as being "hospital records" from which "the prevalence and incidence of mental health" can presumably be derived. It further points out that

the basic ideas to be resolved before comparisons (among different countries) are possible are: (a) agreement about what constitutes a case of specific type of mental disorder, (b) development of standardized case-finding methods for detecting cases in the various population groups and standardized methods of classification, (c) devising standardized methods for measuring duration of illness and for characterizing the psychological status, the degree of psychiatric disability, social and familial adjustment, and physical condition at various intervals following onset of disease.

Further on, reference is made to the "need" to study "genetic and prenatal factors."

These references made to the Senate Subcommittee's report, much of which echoes similar ones emanating from the World Health Organization are cited to illustrate the kind of assumptions made by many public health people about "mental illness." The errors are certainly not those of the public health specialists, but of the arbitrary administrative practices of psychiatrists who have created the records from which these assumptions have been made. Not all psychiatrists view "mental illness" in this way, but there are some, particularly in the public mental health field, who employ a language similar to that with which statisticians and epidemiologists are familiar, and their reports are taken at face value. These psychiatrists speak of concepts such as "illness," "case finding," "incidence,"

"etiology," "epidemiology," "physical condition," "frequency," "diagnostic classifications," "clinical manifestations," "hospital records," "genetics" and "pre-natal influences" in such a way as to imply that psychiatric disorders are comparable to infectious diseases. The expectation lying behind "epidemiological" investigations of both sorts is that of finding some "etiological agent" or "mode of transmission," with the assumption that it will be found in some germ, vector, nutritional factor, or in genetics.

There is another way of looking at the phenomena of psychiatric disorders which make very inappropriate the assumptions outlined above. This point-of-view sees psychiatric problems as being man-made rather than biologically determined, and as such are comparable to studies of such man-made phenomena as art, literature, government and crime and not comparable to studies of biologically determined problems, such as malaria, vitamin deficiencies or cancer. From this viewpoint, the "incidence" of mental illness would be studied in much the same way that we would study the "incidence" of communism, or lynchings, or murders, or poverty or illiteracy. Likewise, the "etiology" of the former will be found from sources similar to that of the latter. Statistics pertaining to both need to be viewed according to similar qualifying conditions.

INTERPRETATION OF MENTAL HEALTH STATISTICS

Much of the public health effort in the field of mental health is directed at studies of the "diagnostic" classifications of mental disorders. The National Institutes of Health are conducting a large-scale program along these lines, and there is a conspicuous absence of a recognition of the true nature of these alleged "diagnoses." Again, "diagnoses" are made in the mental health field only because it happens that physicians make them, and physicians characteristically classify persons according to this concept. To a physician, for example, a healthy, normal person would be classified as: "Diagnosis: No disease." To a certain, well-known pathologist, an ordinary woman is "a constipated biped with a low-back pain."

Actually, the diagnoses used in the field

of psychiatry convey very little useful meaning, and none for which any significant "epidemiological" implications can be derived. A person who is admitted to a mental institution, for example, is most likely to be "diagnosed" as some sort of psychosis because this justifies the deprivation of human rights which is incident to admission to a mental hospital. Similarly, people about whom a decision is made to *not* admit them to a mental hospital are seldom classified as psychotic because to do so would require an elaborate justification for not making the commitment.

In addition to this general classification, specific "diagnoses" are arrived at, to a large extent, by arbitrary administrative rules and by the varying points of view of different psychiatrists. For example, in some states there exist administrative prohibitions against the admission to state hospitals of problems associated with alcohol. As a result, in those states, the term "alcoholism" seldom appears in any list of hospital patients' diagnoses, although there can be found many examples in those hospitals of patients who, under other circumstances would be listed under "chronic alcoholism" or "alcoholic psychosis." In many places, the most available beds for the care of the social or medical problems associated with aging are the mental hospitals, and in these cases as many as 30-50% of all admissions might be listed as "cerebral arteriosclerosis," "senility," etc. in order to justify the admission, and not because there exists a unique psychiatric disorder requiring care in the mental hospital. It is not uncommon, in a given hospital, for the ratio of "schizophrenia" to "manic-depressive psychosis" to change drastically when a new administrator takes over the direction of the hospital, if he has a different type of diagnostic preference than his predecessor. The difference between the two "diagnoses" is a descriptive one, and one can arrive at one instead of the other according to which features of a patient one emphasizes.

Another factor of great importance in assessing the reliability of "diagnostic" data in "mental illness" is often unrecognized. In the various states of the U. S. there is a wide range in the number of mental hospital beds per 100,000 population which the

state legislatures are willing to provide money for. This wide range (in the order of 500%) is determined by economic and political forces, and not by public health need. In each state, regardless of the number of beds provided, they are always filled. As a matter of fact, the average bed occupancy rate is over 100%. When investigators seek to learn about the "incidence" of mental disorders in a population by studying the admissions to the public mental hospitals, they only discover the number of patients who get into the hospitals, and not the number of patients who need hospitals. In a state, for example, which previously provided one mental hospital for its people but which subsequently builds a second one, the number and rate of hospitalized patients in the state almost immediately doubles, because of the tendency of new hospitals to become filled very rapidly. This abrupt change obviously does not reflect a doubling of the "incidence" in the population, but rather a doubling of the number of available beds. Because hospital statistics show only the number of beds provided, and not the "incidence" of mental difficulties in the population, we could expect that they would reflect most accurately the level of financial resources of the states. Other countries demonstrate the same correlation. Consistently, the most prosperous countries, states, cities or provinces provide the most extensive psychiatric facilities, which are almost invariably utilized to the saturation point. The fact that psychiatric facilities are utilized to a maximum degree in each instance is a good clue to the fact that the data reflects only the degree of utilization, and not the "incidence."

There also exists a very wide range in what might be called the "psychiatric sophistication" of various populations. In some areas people have learned to look upon "psychiatry" with a much greater degree of sophistication than in other areas. People in such cities as New York, Boston, Washington and Topeka, and particularly in the middle class suburban areas of these cities show a high level of this "psychiatric sophistication," chiefly because these areas have become the centers of the greatest concentration of non-institutional psychiatrists.

The proximity of these specialists has resulted through the years in educating the lay population in the commonplace, everyday, use of psychiatric services outside of the institutions. The resulting sense of familiarity produces greater acceptance. In contrast, there are other areas, particularly in the southern and western states (except California), even large cities, where there has not developed a high concentration of non-institutional psychiatrists. As a result, the local public's image of psychiatry is likely to be limited to that portrayed by local mental hospitals. This kind of picture generally makes for fear and prejudice, even in otherwise well-educated populations. In addition, of course, there is a sizable segment of the population which is simply ignorant of the whole subject of psychiatry, and scarcely knows of its existence or purposes. We might, therefore, describe 3 levels of "psychiatric sophistication." The 1st level would characterize population groups who are relatively well-informed about non-institutional psychiatry and likely to accept it as a commonplace medical service. The 2nd class is comprised of those whose experiences have been confined to remote contacts with institutional psychiatry which tends to leave them with substantial prejudices against its use in everyday affairs. The 3rd level is made up of those persons who have had so little experience with any type of psychiatry that they are essentially ignorant of it. There will be found a high degree of correlation between the distribution of these different types of population and the different types of psychiatrists. The 1st class will be found in the region of 10 or so large cities in which non-institutional psychiatrists have become concentrated. The 2nd class will be found mostly in those areas where psychiatry is represented chiefly by the state hospitals. And the 3rd class is found in those areas where psychiatry is almost completely inconspicuous.

The degree of "psychiatric sophistication" in a given population will have a very marked influence on the nature of "mental health statistics." The latter must be interpreted in the light of the former. In those communities where there exists an extensive number of non-institutional psychiatric re-

sources (clinics, general hospital psychiatric services, private psychiatrists), there rapidly develops a high level of "psychiatric sophistication." The resulting acceptance of psychiatry leads to a much greater use of these facilities for the relatively minor, early cases of psychiatric disorder. This trend becomes particularly evident in the use of these facilities for childhood psychiatric problems. In contrast, those communities where the public image is dominated by the public mental hospitals, and the level of sophistication correspondingly low, there is not likely to be a noticeable demand for treatment of these early, relatively uncomplicated problems. Instead, people are unlikely to avail themselves of service until the clinical condition has reached such a serious state that institutionalization appears to be the only available solution. Examination of the "mental health statistics" of these two communities will reveal what appears to be two entirely different "epidemiological" pictures. In the first case, it would appear that there is a much higher "incidence" of childhood psychiatric problems, of neurosis, of early schizophrenia, *etc.* In the other case, we would expect to find psychiatric disorders appearing in the older age groups, and to be predominantly psychosis instead of neurosis. In brief, "psychiatric sophistication" of the population will be one of the variables which contribute to a distortion of the apparent "epidemiological" picture of mental health.

What can we say, then, about the true frequency of mental disorders in a population? Is there a way of making a valid estimate in spite of the unreliability of the data customarily used? The answer is "no," simply because the "incidence" is an arbitrary, social decision, and not one resulting from "cause and effect" phenomena. In contrast, conditions such as typhoid fever are absolute in the sense that a given individual either has or does not have it, thus making it possible to count accurately those who do. Psychiatric disorders, on the other hand are relative and qualitative so that their numbers are determined by social criteria which are essentially unrelated to clinical realities. Any given society decides that there are certain limits of human behavior which are acceptable to that society, and that the in-

dividuals whose behavior falls outside those limits are regarded as unacceptable, or "abnormal." This sort of delimitation means that in any given social group, a certain percentage of its members will fall into the "abnormal" category, and become, therefore, subject to psychiatric, legalistic or economic segregation. The indigent, the criminals, the mentally retarded, as well as the so-called "mentally ill" must be seen as the total number which make up this unacceptable segment. The standards established are determined by many factors, not the least of which is the degree of willingness and ability of the community to support a dependent population. In societies which are willing and able to afford the costs of supporting large numbers of unproductive citizens, there will be a high rate of institutionalization. Other societies which are less able or less willing to pay a high price will institutionalize smaller numbers. The types of institutions among which this segment of dependent people are divided up will be determined by another set of arbitrary factors. Some communities make more extensive provisions for the indigent than they do for psychiatric problems, so that their apparent "incidence" of psychiatric disabilities will appear to be low. The state of Wisconsin is an example of this. Other states, or communities, such as New York, have emphasized the development of mental institutions at the expense of provisions for the indigent, and their apparent "incidence" will appear to be high (500% higher, as a matter of fact). Some southern states are more likely to shunt their unwanted social problems to penal institutions, thus reducing the apparent percentages going into mental hospitals. Washington, D. C. is an example of a community where the arbitrary interpretation of certain laws by a handful of judges and psychiatrists have produced wide fluctuations in the numbers of people going to penal institutions on the one hand, or mental hospitals on the other.

Highly urbanized, the older and more prosperous communities tend to set up stricter standards for what is considered "normal" behavior than do more rural, newer or less prosperous communities. This results in apparent differences in the "incidence of mental illness," as well as differ-

ences in the apparent rates of juvenile delinquency, alcoholism and crime.

Another variable of great importance is the issue of whether social problems come to the attention of public authorities, or are handled privately. Certain groups of people, such as the Chinese, the Mennonites, and the sophisticated upper middle class tend to "take care of their own." Resources within these cultures are used to handle individual problems so that they are not so likely to come to public attention, and thus become part of the "statistics." On the other hand, certain population groups tend to rely very heavily on public resources, and these are most likely to be those whose economic, educational, and living arrangements fail to make room for their unproductive members. These population groups will, therefore, contribute large numbers to the published "statistics."

Still another variable of expanding significance is the proportion of the aged population in a society, the nature of the provisions made for their care, and the attitude of younger people toward assuming responsibility for their older relatives. Communities with a high percentage of aged people, with inadequate provisions for their specialized care, and with prevalent attitudes sanctioning the abandonment of the aged from the homes of the younger tend to contribute large numbers of "cases" to the lists of "mental illness." New York City is an example of these combined factors. There, nearly 50% of admissions to local state hospitals are people over 65, even though only 11% of the population is in this age group. In contrast, England and the Scandinavian countries have a much higher percentage of aged people in the population, but a much lower proportion of aged in the mental hospital admissions, both being in the order of 12-14%. These countries have made better provision for the non-hospital care of their aged, and their younger people are less disposed to abandon aged relatives. These two sets of social attitudes and practices make for very wide differences in the apparent "incidence" of mental disorders in the two cultures, introducing a possible error of as much as 300-400% if statistics are taken at face value.

SUMMARY

The actual way in which our "mental health statistics" came to be what they are is not through the process of "detecting" a certain number of "cases" in a population as a result of "hospitalization." Instead, the figures which are published are reflections of many variables determined by different and complex social attitudes and socio-economic practices. The most significant factor which is revealed by mental health figures is the degree of hospital utilization, and not hospital need.

The remarkable successes which the public health people have achieved in the past in conquering many of our major health problems have left them with the time and resources to tackle new problems. They are now shifting their interest to the mental health field, and therefore represent one of psychiatry's most important potential allies. It behooves psychiatry to join forces with them. The new interdisciplinary frontier which is opening up, places on psychiatry's shoulders the responsibility of clarifying some of the misconceptions which are current. The true meaning of "mental health statistics" is one which only psychiatrists can interpret correctly. Like so much of what we say and write in psychiatric circles, they should not be taken at face value. The remarks made in this paper are designed to point the way toward a clarification of some of the contradictions which may not be apparent to public health workers.

It is only fair to point out, however, that within the field of psychiatry there exists a point of view which would disagree with the above interpretations. This viewpoint is represented by those psychiatrists who see "mental illness" as an all-or-none pathological state comparable to contagious diseases, for example. It is largely from these psychiatrists that the data from which the new "epidemiological" studies are derived are being produced. When the public health worker seeks to interpret these data, he will be confronted with the dilemma of an old psychiatric controversy. We can only extend our sympathies to the poor investigator who finds himself innocently caught in the middle.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

A CONTROLLED CLINICAL STUDY OF CHLORDIAZEPOXIDE

ALLAN Z. SCHWARTZBERG, M.D.,¹ AND ROBERT W. VAN DE CASTLE, Ph.D.²

Chlordiazepoxide (Librium)³ has recently been reported (1, 2) to represent an important advance in the psychopharmacologic approach to psychiatric disorders, particularly useful in anxiety, fear, and tension states.

METHODS AND MATERIALS

Twenty-one patients with a diagnosis of psychoneurosis or personality disorder with significant anxiety and tension components were selected. The patients were divided into 3 groups, carefully matched, on the basis of clinical impressions and Minnesota Multiphasic Personality Inventory scores. Each patient served as his own control and received a 2-week supply of either Librium, 10 mg.; meprobamate, 400 mg.; or placebo, in identical capsules, t.i.d. The patients were instructed to adhere carefully to the medication schedule and were allowed to reduce the dosage if significant side effects occurred.

Prior to administration of this drug, each patient completed the following tests: 1. Symptom Check List (3) (a clinical "weighted" questionnaire of 50 items categorizing symptoms under the major areas of psychopathology); 2. Anagram Test (4) (a test representing the number of anagrams successfully solved during a 5-minute period (maximum of 15 words)); 3. Pursuit Rotor Test (5) (a test measuring motor manifestations of anxiety). These tests were repeated at 2-week intervals, in addition to brief psychiatric interviews, to assess the patient's own evaluation of the drug. No attempt was made to do psychotherapy dur-

ing the period of drug therapy, and the doctor-patient relationship was kept at a minimum.

RESULTS

TABLE 1

Mean Scores on Various Anxiety Indices

	Placebo	Meprobamate	Librium
Symptom Check List	47.95	47.00	46.35
Pursuit Rotor Test	1500.20	1625.78	1552.68
Anagram Test	7.10	6.74	6.68

The mean scores for the various anxiety indices are reported in Table 1. The Pursuit Rotor scores refer to the length of time that a patient kept a stylus in contact with a small revolving metal disk during a 4-minute testing session. Scores are expressed in units of 1/1000 of a minute. Differences between the mean scores were evaluated by an analysis of variance technique. None of the resulting F ratios reached the 0.05 level of statistical significance for any of the 3 anxiety indices.

TABLE 2

Mean Scores on Various Anxiety Indices as a Function of Time

	Pre-Drug	Two-Week	Four-Week	Six-Week
Symptom Check List	63.37	54.16	46.90	40.60
Pursuit Rotor Test	743.90	1013.11	1504.37	2128.15
Anagram Test	6.15	7.00	5.47	8.00

The mean scores for the various anxiety indices comparing the pre-drug effects with the results at 2-week intervals are presented in Table 2. No systematic changes were noted for anagram scores, since success appeared to be related to the difficulty of the separate anagram lists. The changes toward improvement on the Pursuit Rotor scores

were significantly different at less than the 0.01 level, when evaluated by an analysis of variance technique. Since this task is also frequently used as a measure of learning, it is not possible to state how much improvement in scores could be traceable to the effects of learning on task performance.

DISCUSSION

A question might be raised as to whether the mean scores in Table 1 might have been unduly influenced by the scores of a few atypical patients. To analyze this factor, a comparison was made of the number of patients whose symptom check-list scores decreased from their initial pre-drug scores. Only 1 patient did not complete the study. It was found that 79% of patients reported improvement (lower check-list scores) while receiving a placebo, 89% with meprobamate, and 74% with Librium. Since so many patients reported improvement beyond their pre-drug status even with a placebo, it is possible that changes in anxiety indices may have occurred as a simple function of participating in a drug study.

In Table 2 we noted that a progressive decrease in the number of symptoms occurred with progression of the study. Not only the severity of the individual symptom but also the number of symptoms markedly declined. The difference between the pre-drug symptom check-list scores and those

obtained at the termination of the study was significant beyond the 0.05 level when evaluated by a *t* test. This latter finding points toward the necessity of control groups in drug research, since it would be possible to demonstrate a significant decrease in symptoms merely through participation in a drug study without obtaining evidence that the effects were due primarily to the drug itself. The study proceeded with minimal dosages throughout. It is entirely possible that different effects would have been obtained if different dosage levels had been employed. Clinical experience with Librium at dosages of 60 mg. and higher has shown more favorable results in symptomatic relief of anxiety than with the dosage used in the study. Two patients reported drowsiness while receiving Librium, but no other significant side effects were noted with any of the drugs.

CLINICAL REPORT ON METHAMINODIAZEPOXIDE (LIBRIUM)

ROBERT R. SCHOPBACH, M.D.¹

Methaminodiazepoxide (Librium)² was prescribed for 53 consecutive suitable patients seen in a big city outpatient clinic. Most of this group had symptoms of long standing and had been unsuccessful in obtaining relief from other drugs and psychotherapy; 15 were obsessive compulsive perfectionists. Because of this failure to respond to previous therapies it may be permissible to consider them their own controls

and to rule out placebo effects although in a few cases placebos were utilized. The usual dose was 10 mg. q.i.d. Periodic blood counts, urinalyses, and transaminase determinations failed to reveal any toxicity. Two patients discontinued the medication due to nausea and vomiting but one of these had the same symptoms with placebos. Other than slight drowsiness, which was relieved by decreasing the dosage, no other side effects were noted at this dosage level.

The results (Table 1) are tabulated as (0) unimproved; (+1) slight improvement

¹ Associate in Psychiatry, Henry Ford Hospital, Detroit 2, Mich.

TABLE 1

Result	Obsessive-Compulsive	Depression	Anxiety & Others	Total
0	4	2	12	16*
+1	1	4	1	6
+2	1	1	5	6
+3	1	3	5	9
+4	8	1	5	13
	15	11	28	50

* Some patients were both obsessive-compulsive and depressed so the total does not include them twice.

—loss of a minor symptom or slight reduction in anxiety level (one patient had to discontinue then recommence the drug to be certain of any benefit); (+2) moderate improvement; (+3) marked improvement —only minor symptoms or minimal anxiety remained; (+4) complete relief. Three patients were excluded because psychotherapy and/or concomitant medications confused the issue; however all 3 showed at least moderate improvement. If only those markedly or completely relieved are considered, and that is the least degree of help which really satisfies the patient, this drug was effective in 44%. Although this figure is low it must be remembered that these were chronic neurotics who had not responded to other therapies. Nine (60%) of the 15 obsessive-compulsive patients achieved this

marked or complete relief. This is an excellent result in a condition usually so resistant to therapy. One man was about to sell out his interest in a furniture store because he could not make decisions, talk reasonably with customers, and was becoming severely hypertensive. He is now functioning with pleasant efficiency and his blood pressure fell to 140/90. "I no longer fear to tackle problems." Another worrywart stated, "I feel perfect now. I am able to do things without worrying back and forth first." Of the 11 depressed patients selected because they were fearful, fretful or guilt-ridden, only 1 was completely relieved but 3 more were markedly helped. Librium is not suggested as the drug of choice for depressions but in selected cases may be of definite value in reducing such symptoms when given in addition to other therapies for the depression.

SUMMARY

Methaminodiazepoxide (Librium) was beneficial for 60% of obsessive compulsive patients and for about one-third of others suffering from chronic neuroses and/or depression. These benefits achieved by patients previously considered therapeutically unpromising indicate that this drug is a valuable addition to our armamentarium. In the dosage of 10 mgm. q.i.d. side effects were minimal.

THE CAUSE OF FALSE-POSITIVE TESTS FOR PIPERAZINE-LINKED PHENOTHIAZINES

JACK J. HEYMAN, M.S., AND SIDNEY MERLIS, M.D.¹

During the past several years there has been great interest in simple methods of checking phenothiazine intake in patients. While these tests have been used with a moderate degree of success in many laboratories, the occurrence of false-positive results with some of the more recent of the phenothiazine preparations has been reported (1, 2). We have isolated from urine samples a compound that produces false-positive results with Forrests' test¹ for piperazine-linked phenothiazine reagent (3) but not with Forrests' Thorazine reagent (4).

During the past several years there has been great interest in simple methods of checking phenothiazine intake in patients. While these tests have been used with a moderate degree of success in many laboratories, the occurrence of false-positive results with some of the more recent of the phenothiazine preparations has been reported (1, 2). We have isolated from urine samples a compound that produces false-positive results with Forrests' test¹ for piperazine-linked phenothiazine reagent (3) but not with Forrests' Thorazine reagent (4).

METHOD

The isolation was carried out on normal individuals who had never taken phenothiazine compounds of any description and on patients who had currently been on phenothiazines. The normals' age range: 22 to 42 years; the patients': 30 to 50.

The isolation procedure consisted of dissolving 23 g. of anhydrous sodium sulfate per 100 ml. of urine and 6 g. of dibasic

¹ Research Division, Central Islip State Hospital, Central Islip, N. Y.

sodium phosphate (Na_2HPO_4) per 100 ml. of urine. The pH was adjusted to 11.5. The adjusted urine was then shaken with n-butanol in a separatory funnel. The butanol layer was separated and was stored overnight under refrigeration.

The clear amber-colored butanol was tested for its color development with 3 different reagents. The procedures were: 1. 2 ml. of concentrated nitric acid were added to 10 ml. of the butanol extract. The samples were read in a Klett colorimeter with a green filter against a butanol-acid blank. 2. A 5-ml. butanol sample of extract was treated with 5 ml. of Forreests' Thorazine reagent. The samples were read using a green filter. The blank was butanol-Forreests' Thorazine reagent. 3. A 10-ml. sample of the butanol extract was treated with 2 ml. of Forreests' mercuric nitrate reagent. The samples were read on a Klett with a blue filter against a butanol-reagent blank. The Klett readings reported were computed from the observed reading corrected for the volume of the 24-hour urine samples compared.

RESULTS

The results in Table 1 indicate that the compound extracted gives very significant color development with the mercuric nitrate reagent. It produces much less color with the Forrest Thorazine reagent. In other experiments we have observed that increasing the sulfuric acid above 20% increases the color development. In our study, using ion-exchange resin papers impregnated with ferric chloride, we observed that urine samples treated with 50% sulfuric acid produced close to 100% false-positives even when the source of the urine was from the normals. Forrest indicated a similar role for the tri-

chloracetic acid with the mercuric nitrate reagent(3).

The chemical and physical characteristics of the isolated compound are as follows: the uncorrected MP is 130-131°. Sodium fusion tests reveal that the compound contains nitrogen, but no sulfur or halogen. It is not optically active and does not fluoresce. The compound has an average rf of .96 in n-propanol-.2N NH_4OH (1:3 v/v), using the technique described by Kapeller-Adler and Iggo(5). If the butanol extract is washed with .5N HCl and allowed to stand in air it changes in color from amber to green to blue to red over the course of several days. While this behavior is suggestive of a porphyrin, the compound fails to give a Soret band and is, therefore, probably not a porphyrin-type compound. The UV spectra do not demonstrate adsorption characteristic of either an indole or a pyridine. The compound couples with diazotized sulfanilic acid to give an orange color. With concentrated nitric acid a violet color changing to a red brown is observed. It precipitates as a red-colored salt. It is Biuret-negative. With the mercuric nitrate reagent it gives a violet-blue color. With concentrated HCl it gives a peach color which turns violet. With 3% hydrogen peroxide and concentrated HCl it gives a violet color.

CONCLUSION

We have isolated a compound which is probably responsible for the observation of false-positive phenothiazine tests not attributable to acute or chronic liver disease, phenylketonuria, high salicylate or other drug intake(6). Since the isolated compound produces color with nitric acid it may interfere with Forreests' FPN reagent (7) and Neve's test(8). The isolated com-

THE INFLUENCE OF CORTISONE-ACETATE ON SOME SERUM PHOSPHORUS METABOLITES IN YOUNG MALE SCHIZOPHRENICS

PAUL KOCH, Ph.D., CAMILLE LAURIN, M.D., AND ROGER LEMIEUX, M.D.¹

This study is part of a research undertaken to establish, if possible, simple biochemical differences between schizophrenic and non-schizophrenic psychiatric patients. Tests based on such differences could serve to circumscribe more closely the clinical diagnosis and would permit screening for schizophrenia among newly admitted patients.

This paper deals with differences in some serum phosphorus metabolites found after stimulation with cortisone acetate² between 2 comparable groups of schizophrenics and non-schizophrenics.

Considerable evidence has been accumulated that schizophrenics react differently to stress (1, 2) and to ACTH and Corticoids (2, 3, 4, 5). The most striking difference of reaction that has come to our knowledge has been an abundant phosphaturia induced in schizophrenics by ACTH (1, 2). Similar phosphaturias could be induced by ACTH in human volunteers (1) as well as in guinea pigs (6) after the administration of the hallucinogene LSD-25. Stevenson, *et al.* (7), Lovegrove, *et al.* (8), as well as ourselves (9) have tried to utilize the corticoid-induced phosphaturias as a biochemical test for schizophrenia but with disappointing results.

It was thought that the phosphaturias probably originate in some serum phosphorus metabolites. Therefore it was decided to study the mineral phosphorus, the total acid soluble phosphorus, the lipid phosphorus and the alkaline phosphatases in the serum of schizophrenics, following administration of cortisone.

MATERIALS AND METHODS

Thirteen male schizophrenics, aged 20-40, suffering from various types of the disease, were compared with a corresponding control group of 13 young male patients, suffering from other psychiatric syndromes. It was found necessary, later on, to add to the experiment a third group which consisted of 7 young male schizophrenics and which served as a double placebo² control.

On the first day all medication was suspended at noon and was not resumed until after the end of the experiment. However, the subjects received, each night, 200 mg. chloral hydrate to ensure sleep. Fasting was enforced every day after supper and lasting until noon of the following day.

On the second day blood was drawn at 9:00 a.m. and a placebo was given. Blood was drawn again at 10:00 a.m. and at 11:00 a.m. Food was permitted at noon.

On the third day the same routine was followed as on the second day. The placebo was substituted by a pill, containing 100 mg. cortisone acetate. The nature of the pill was not known to anyone having direct contact with the patients.

Because of the long lasting effect of corti-

¹ Albeft Prevost Institute, 6555 Gouin Blvd. W., Montreal, Canada.

² We wish to thank Merck & Co. for the gracious gift of the cortisone acetate and the placebos, as well as Miss Fernande Bastien for her capable technical assistance.

sone, no inversion in the order of the treatments was attempted. For this reason a third group of schizophrenics has been added, which received placebos on both days. This was done to find out whether any variations of phosphorus metabolites could be due only to the withdrawal of the medication.

Twenty ml. of blood were drawn each time. Ten ml. were destined for serum (mineral phosphorus and alkaline phosphatases), while 10 ml. were received into an ice cooled test tube containing versenate as an anticoagulant. This sample was processed very rapidly to furnish plasma (acid soluble phosphorus and lipid phosphorus). All analytical methods were standard procedures (10).

Since very little difference seemed to exist between the samples taken at 10:00 a.m. and those taken at 11:00 a.m., their arithmetical means have been used in the results in order to simplify their presentation.

DISCUSSION AND CONCLUSIONS

Cortisone does not vary any of the phosphorus metabolites investigated in the blood of the non-schizophrenic controls. In the schizophrenic experimental group it decreases the lipid phosphorus at the 5% level and increases the alkaline phosphatases at the 2% level of significance. That this variation is due to cortisone and not to the suspension of the medication has been shown

by the third group. There was no variation of any metabolites studied.

The levels of the alkaline phosphatases appear quite low. It has been our experience in routine laboratory work that phenothiazines tend to depress the phosphatase level in the absence of hepatic involvement. This depression is quite persistent.

Comparing the increase of the phosphatases with the decrease of the phospholipids one cannot help speculating whether the 2 phenomena are not connected.

A broader study is now in progress involving a similar group as well as older patients and women.

SUMMARY

Oral cortisone acetate can differentiate between young male schizophrenics and a comparable control group by inducing an increase in alkaline phosphatases and a decrease in phospholipids in the former. No such changes were observed in the latter group.

EFFECT OF THE COMBINED ADMINISTRATION OF IMIPRAMINE AND A MONOAMINE OXIDASE INHIBITOR

WILLIAMINA A. HIMWICH, Ph.D., AND JOANN C. PETERSEN, B.A.¹

We have been encouraged to publish a brief note on our animal experiments by the recent clinical reports(1, 2) of disastrous results from the combination of imipramine (Tofranil, Geigy) and a monoamine oxidase inhibitor. Over the past year a series of dogs has been given a combination of imipramine followed by a monoamine oxidase inhibitor, tranylcypromine (Parnate, Smith Kline & French). Our animals were routinely treated daily for 5 days with an intramuscular injection of 10 mg./kg. of imipramine dissolved in water. Behaviorally, this medication appeared to have little effect, especially if the animals were exposed to the stimulus of cage mates or animals in adjacent cages. However, in a quiet room it could be noted that chronic imipramine administration resulted in a tendency for the animal to drowse. On the fifth day the intramuscular injections of imipramine was followed immediately by the intravenous administration of 2 mg./kg. of tranylcypromine. The behavioral results of this combined medication and the effect upon serotonin content of the brain have been described in detail elsewhere(3). It is sufficient to note here that the animal appeared drowsy at first—about 2 hours later both males and females showed rhythmic twitching of the hind legs. In the males this twitching progressed to repeated sexual orgasms, whereas in the female, although the twitching slowly became more violent and more rhythmic, no sexual orgasms were ob-

served. As has been reported in human patients, some animals receiving imipramine and tranylcypromine showed marked hyperthermia and profound salivation. If the same animals were given the identical drug schedule, but with chlorpromazine (Thorazine, Smith Kline & French) replacing imipramine, no disturbances were noted. Chlorpromazine appeared to make the animal somewhat sedated on the first day of administration, but after that had little effect. The addition of tranylcypromine to chlorpromazine evoked no unusual behavioral picture.

EEG's were recorded from the areas of the right and left motor cortex by means of silver ball electrodes chronically implanted on the surface of the dura in animals receiving 1. Imipramine alone for 4 days, 2. Imipramine and tranylcypromine on the schedule given above, or 3. A single dose of tranylcypromine. The EEG recordings show that there was a tendency for the animals receiving imipramine alone to sleep more readily than the untreated animals and to be less easily aroused from sleep by auditory stimulation. In animals which received tranylcypromine following imipramine, the EEG drowsy picture lasted longer than with imipramine alone. The record then progressed to marked alert activity in the cortex accompanying the orgasm, or, in the case of the female in association with the rhythmic twitchings of the hind legs. The EEG alert pattern appeared spontaneously at a time immediately previous to which an alert EEG could not be evoked by means of external stimuli such as a hand clap.

¹ Thudichum Psychiatric Research Laboratory, Galesburg State Research Hospital, Galesburg, Ill.

After the disappearance of gross motor activity, which may last for as much as 2 hours, the animals again were asleep and exhibited a drowsy EEG pattern which could not be changed by auditory stimulation.

EEG recordings of animals given chlorpromazine alone showed a typical drowsy-like state similar to that following imipramine. The addition of tranlycypromine after chlorpromazine resulted in sleep during which an arousal response could be elicited by a hand clap. Tranlycypromine alone produced in the dog an EEG tracing which was only slightly more desynchronized

(alert) than normal. Behaviorally, the animals seemed tense, restless and easily stimulated by environmental conditions. Our studies are continuing along this line in an attempt to explain the clinical results obtained in some patients when imipramine is combined with a monoamine inhibitor.

COMPARISON OF MARPLAN AND TOFRANIL IN THE TREATMENT OF DEPRESSIVE STATES

JANE E. OLTMAN, M.D., AND SAMUEL FRIEDMAN, M.D.¹

This comparative study of Marplan, a monoamine oxidase inhibitor type of antidepressant drug, and Tofranil, a non-MAO inhibitor, has been conducted during the past 8 months. The material consisted of female patients, newly admitted to the hospital and suffering from acute or recurrent depressive illnesses. There were 120 individual patients in the study; however, because some patients underwent treatment with both drugs in tandem or because of occurrences of 2 discrete episodes of illness during the study period, there was a final total of 140 treatment periods, with 70 patients in each drug group. Distribution by age and diagnostic category was essentially identical for both groups. Marplan was used in initial dosage of 30 mgm. daily, with increase to 60 mgm. daily, usually within the first week; Tofranil was used in dosage varying from 100 to 200 mgm. daily, most frequently at a level of 150 to 200 mgm. daily.

Results were designated as satisfactory (A level) for patients who achieved a remission or much improved status, and as unsatisfactory (B level) for those who failed to improve, or exhibited partial improvement only. Final results were very similar in

both drug groups. In the Marplan group, 51 of the 70 patients, or 72.9%, achieved an A level of improvement, and in the Tofranil group, 50 of the 70 individuals, or 71.4%, attained a similar level. It may be noted also that the results in the current Marplan group were practically identical with those previously reported² in a group of female patients treated with this drug.

With respect to the rapidity of improvement, it appeared that, in general, Tofranil produced a slightly more rapid effect. Thus in patients successfully treated with Tofranil, satisfactory improvement was noted temporally in the following cumulative manner: in 2 weeks, 11%; in 3 weeks, 38%; in 4 weeks, 72%. For the Marplan group, the corresponding figures were: in 2 weeks, 3%; in 3 weeks, 12%; in 4 weeks, 52%. Thus only 28% of the Tofranil group required more than 4 weeks for the establishment of satisfactory improvement as compared with 48% of the Marplan group. By the end of the fifth week, however, the cumulative percentage of satisfactory results was again very similar in both groups, namely, about 80%. Thus, on an average, Tofranil appeared to exert its optimal effect in favor-

² Oltman, J. E., and Friedman, S. : (a) *Am. J. Psychiat.*, 116 : 848, 1960. (b) *Dis. Nerv. System*, 21 : Supp., March 1960.

¹ Fairfield State Hospital, Newtown, Conn.

able cases possibly 5 to 6 days sooner than did Marplan. A further advantage of Tofranil was its availability in parenteral form.

Some patients who failed to improve satisfactorily under one drug did so on the other. Thus 6 patients who were regarded as failures under Tofranil therapy achieved a successful result with Marplan, and conversely, 5 patients who were therapeutic failures with Marplan, improved satisfactorily under Tofranil. Seven patients failed to improve under both drugs used in tandem, and 2 patients achieved a remission under each drug used separately in 2 discrete episodes of illness.

With respect to the incidence of complications, it may be stated that there were no serious complications in either group. The incidence of side-effects, although these were rarely excessively troublesome, ap-

peared to be slightly higher in the Tofranil group. In this group the following number of complaints or side-effects appeared: edema, 2; dizziness, lightheadedness, *etc.*, 15; excessive perspiration, 9; constipation, 4; neuralgia, 2; skin eruption, 1; incontinence, 1; tremors, 1; dry or peculiar taste in mouth, 3; and manic swing, 2. In the Marplan group there were: edema, 10; dizziness, lightheadedness, *etc.*, 11; excessive perspiration, 1; dryness of mouth, 1; and manic swing, 1. One patient in the Tofranil group suffered a slight fracture of the nasal bone when she fainted during a dizzy spell.

In conclusion, therefore, it may be stated that both Marplan and Tofranil are effective antidepressant drugs. Tofranil appeared to exert its action somewhat more rapidly but, on the other hand, the incidence of side-effects was somewhat greater than with Marplan.

THRESHOLDS FOR DRUG-INDUCED AKATHISIA¹

DANIEL X. FREEDMAN, M.D.,² AND JACOB DE JONG, M.D.³

The critical determinants of drug-induced akathisia have generally been ascribed to the basic phenothiazine structure, particular substitutions on it, and the level, period and rate of increase of the dosage. To determine whether individual factors contribute to the incidence of akathisia, this study was designed to detect sensitive individuals who would develop akathisia on low dosage and early (within 14 days) in the course of phenothiazine administration.

MATERIALS AND METHODS

From hospital records, 31 chronically schizophrenic women were selected as a "presumptively sensitive" group. The mean age was 55 (range 29-76); average length

of hospitalization, 11 years (range 2½-27). Prochlorperazine (Compazine) 10 mg., perphenazine (Trilafon) 4 mg. and thioridazine (Mellaril) 50 mg. were tested in a Latin square design with the notion that the substituent on Mellaril had less akathisia-inducing potency than the piperazine-substituted drugs. These sub-clinical doses (clinically equated for potency) delivered in identical capsules, b.i.d. for 8 days, were then doubled for 4 days and followed by 7 days of meprobamate (Equanil) whereupon the next test sequence began. Akathisia was scored by physicians who, blind to rotations, evaluated rating sheets completed by ward staff who were blind to the rotations and the intent of the study. Scorable symptoms occurred and disappeared within a few days after administration and withdrawal of the phenothiazine compound.

RESULTS

Sixteen of the 31 patients did not develop akathisia. Four patients (Group 1) had akathisia with the 3 drugs tested; they had the most severe disturbances with associated

¹ Supported by USPHS Grant M-1204, N.I.M.H.; Drugs supplied by Mr. S. Gimpel, Sandoz Co.; Dr. R. Burlew, Schering Corp.; and Mr. J. Bird, Smith Kline & French.

³ Physician and Psychiatrist, Fairfield State Hospital, Newtown, Conn.

Parkinsonian symptoms. Four patients (Group 2) developed akathisia only on Trilafon and Compazine. Seven patients (Group 3) developed akathisia on no more than one of the three tested drugs. On repeat study, individuals retained their group membership. In both trials, the time of the initial onset of symptoms (from the 2nd to the 11th days) varied. The duration of such sensitivity groupings is untested beyond a 7-month period and the dose and time parameters used, but the specificity of low-dose akathisia was demonstrated by further re-testing of selected individuals. For each individual in Group 1 a potent phenothiazine was found with which akathisia did not develop.

These patients are not indifferent to the substituent on the phenothiazine nucleus, but rather show specific sensitivity to specific configurations; *i.e.*, these are polysensitive and *not* pansensitive persons. Particular substituents (*e.g.*, piperazine) appear to be specific for a larger number of individuals than other molecular moieties; for a small group of individuals a large but restricted number of different molecular structures would be akathisia-inducing.

Among the 4 groups tested, no differentiating personality features were discerned; such factors await further study. Biological specificity for molecular structure, demonstrated in a number of pharmacologic studies, is evident here for side effects. In view of the relationships between extrapyramidal symptoms and tranquilization (1, 2, 3) the question arises whether phenothiazines

could also have biological specificity with respect to the tranquilizing potency.

SUMMARY

The findings indicate that low-dose akathisia results from an individual's specific sensitivity to a specific molecular configuration. There is a population with a low threshold for the disorder. Thresholds are determined by the spectrum of individual sensitivities for specific molecular configurations, administered in a specified dosage schedule. The incidence and intensity of low-dose akathisia depend on at least 2 factors: the population tested, and specific molecular structure.

TABLE 1
Frequency of Akathisia, Trial 1 or 2

	TOTAL % INDUCED BY DRUGS ³	Groups (N-15)		
		I N-4	II N-4	III N-7

CHLORPROTHIXINE (TARACTAN) AND ISOCARBOXAZID (MARPLAN) IN PSYCHOTIC DEPRESSIONS

HARRY F. DARLING, M.D.¹

Each drug was used as the medication of first choice on 50 ambulatory psychotic depressed patients, in conjunction with definitive psychotherapy. The patients were followed for three months or more, except that patients who showed slight or no improvement (as well as those who became

worse) were put on other therapy when it became evident that no further improvement would occur.

Table 1 shows age, diagnosis, improvement, side effects and duration of illness; only disturbing side effects are listed.

Dosage of Marplan varied between 20 and 60 mg. daily; in almost all cases 30 mg. was used. It was slowly and cautiously de-

EFFECTS OF TRIFLUOPERAZINE IN AGED DEPRESSED FEMALE PATIENTS¹

GEORGE W. BROOKS, M.D., AND M. GLENN MacDONALD, M.D.²

Twelve female patients suffering from manic-depressive or involutional psychoses were selected¹ for study. Four were diagnosed manic-depressive reaction, depressed type, 8 were diagnosed involutional psychotic reaction. Age range: 60 to 74, average 68 years. Hospitalization was between

able, between 30 and 400 mg. daily, and seemed to vary with the type of depressive syndrome as well as with the individual patient. In general the extremely agitated, active, insomniac patient took a lower dose than the quiet, unresponsive, listless patient, although there were exceptions. When a higher dose was used in this latter type of patient disturbing drowsiness was prone to occur; indeed 5 of the 6 patients who became disturbingly drowsy were of this type. Temporary drowsiness controlled by reduction of dose is not tabulated; there were 11 such cases. Two marked and 1 moderate improvements on Taractan were only temporary.

Concomitantly with dosage was also noticed a difference in improvement between the agitated and the non-agitated patients. Of the 29 patients who improved markedly with Marplan, 21 were not agitated. Of the 31 patients who improved markedly with Taractan, 20 were agitated. Possibly because they had schizoid features, 4 of the 5 patients who became worse with Taractan were involutional.

CONCLUSION

Of the 2 drugs, Marplan seems more indicated as the drug of choice for the non-agitated endogenous depression, Taractan for agitated depression.

17 and 333 months, averaging 166 months. Eight had received an average of 18 electroshock treatments each. Seven had received other tranquilizers for an average of 32 months each.

Initial evaluation consisted of a review of their histories, physical examinations, blood counts, serum cholesterols, chest x-rays, electrocardiograms, and exercise tests. Pulse, blood pressure, and electrocardiogram were recorded 2 minutes, 4 minutes, and 6 minutes after exercise. Clinical status

¹ Study made possible by USPHS Grant MY-1752-C of the NIMH.

² Respectively, Assistant Professor of Clinical Psychiatry and Clinical Associate in Medicine, University of Vermont College of Medicine, Burlington.

and blood counts were reviewed weekly. A second exercise test was performed after the fourth week on trifluoperazine. After the treatment period ended, the initial evaluation procedures were repeated.

Upon completing the first clinical studies, 1 patient was found to have active tuberculosis, 1 had chronic bronchitis and emphysema secondary to severe scoliosis, and another had x-ray and physical findings of emphysema but no respiratory symptoms. One patient had a Parkinsonian tremor. None had findings of cardiac disease, although 2 were previously diagnosed as having arteriosclerotic heart disease and congestive cardiac failure. One of these had been on maintenance doses of digitalis for 40 months which was continued during this study.

Patients receiving other tranquilizers had their medication reduced and then stopped over a period of 1 week. No medication was given for 10 days, then trifluoperazine, 4 mg. daily, was started. On the fifth day, the dose was increased to 7 mg. daily, and on the eleventh day to 10 mg. daily. Four days after the 10 mg. dose, 8 patients required bengtropine to ameliorate signs of Parkinsonism. After 6 weeks of treatment, all were either receiving anti-Parkinsonism medication or had had their trifluoperazine discontinued because of severe Parkinsonism, characterized by cogwheel rigidity and a high incidence of dysphagia. Even after rapid reduction of medication to levels as low as 2 mg. of trifluoperazine daily, rigidity and immobility were not adequately relieved.

The patient with tuberculosis was started on anti-tuberculous treatment, but showed progression of her disease. One became lethargic, looked ill, but no clinical or laboratory findings were present to explain this; she returned to her usual health after

the drug was stopped. One developed a leukopenia of 3,500 at the end of the treatment period. The following week, after trifluoperazine had been stopped, her count rose to 6,000. Another developed an erythematous petechial-type rash over pressure areas. Laboratory findings were normal and the rash disappeared after medication was stopped. There were no significant changes in the physical status of any of the other patients.

Exercise tests were not well standardized for the group due to lack of physical conditioning, coordination, and, in a few, lack of cooperation. Tests failed to reveal evidence of cardiac disease. One developed a nodal tachycardia of short duration immediately after exercise which was not considered significant. Blood cholesterol response was of interest. Eight of 11 patients showed an unexplained drop in serum cholesterol. Two remained the same and 1 increased. The drop ranged from 1 to 150 mg.%, averaging 49 mg.%. Diet, activity, and stress were unchanged during the treatment.

Eight showed no benefit from medication. Three were somewhat more alert, cheerful, and active. One showed dramatic and apparently complete recovery from a severe depression of 8½ years' duration within 10 days after beginning treatment. She left the hospital, continuing medication.

CONCLUSIONS

It would appear that the incidence and severity of Parkinsonism in this age group is so high that trifluoperazine should be used very cautiously. Occurrence of 1 very dramatic recovery and 3 cases of gratifying improvement suggest that trifluoperazine may be useful in cases of chronic depression resistant to more usual therapies.

CASE REPORTS

A NEAR FATAL CASE OF IMIPRAMINE OVERDOSAGE

GENEVIEVE A. ARNESON, M.D.¹

Since imipramine (Tofranil) is being used extensively at the present time for the treatment of patients with depressions,

complications that can result from this medication in overdosage.

Case Report: Patient is a 19-month-old white male who ingested outright, 50-25 mg. imipramine tablets, and sucked the sweet coating off 50 more, getting about half the active ingredient in the process. Patient ate the tablets in the early evening, 7:00-7:30 P.M., on June 13, 1960, while in the care of a baby sitter. The baby sitter noted that the patient looked "funny" and then vomited. She called a neighboring physician who came immediately. By the time he arrived, the patient had begun to convulse. The doctor immediately rushed the child to the New Orleans Charity Hospital. Because of traffic difficulties approximately $\frac{1}{2}$ of an hour elapsed before the child reached the emergency room of the hospital. During this period he was in status epilepticus. Upon reaching the emergency room the patient was immediately intubated, gaged, and given 2½ grs. of sodium amytal, I.V. to control the seizures. Shortly after receiving the amytal, patient's respirations ceased. Artificial respiration was begun and had to be continued over the next 5 hours, before spontaneous respiration returned. Additionally, the patient was exhibiting a marked cardiac arrhythmia. EKG's were taken which showed complete disruption of the normal sinus rhythm, complete heart block, ventricular beats originating from various foci, extremely widened QRS complexes and depressed ST segments. In short, electrical evidence of a marked conduction defect within the cardiac musculature (see Figure 1).

The physicians at the hospital were unfamiliar with the effects of this drug in toxic quantities and were at somewhat of a loss as to how to treat the patient other than symptomatically.

Patient was given 200 cc. of whole blood since systolic blood pressure was 80/? and hematocrit 35%. Additionally, urinary output was poor so that catheterization was required over the next 48 hours. Patient's fluid intake was maintained via intravenous 10% glucose and normal saline. No further sedation was given other than the above mentioned sodium amytal. Hyperpyrexia, methemoglobinemia, and electrolyte disturbances which have been reported did not develop with this patient.

Over the next 24 hours the patient gradually regained consciousness. However, he continued to be drowsy, lethargic, somewhat ataxic and incoordinant, especially on his left side. He tended to have periods of marked irritability, accompanied by involuntary athetoid movements, alternating with deep lethargy, almost

a postictal coma. It was felt that these episodes were some sort of epileptic equivalent. However, within 48 hours the patient was pretty well back to normal, and from this time forward his clinical improvement was rapid and his EKG gradually returned to normal (see Figure 1). The patient was discharged after 7 days of hospitalization and has shown no untoward effects since that time.

DISCUSSION

It is estimated that the child probably ingested about 1,500 mgms. of the drug. Since the ingestion was almost immediately detected, patient vomited, and also was subjected to gastric lavage within an hour and a half after ingestion, it is apparent that this medication is absorbed quite rapidly from the G.I. tract. However, there is no way of knowing how much of the drug was actually absorbed into the blood stream. Even so, it is probably safe to say that patient probably got at least half of the amount ingested. With the child weighing 10 kilograms he thus received a dosage in the amount of 75 mg./kilogram². If we consider this dosage in terms of the acute toxicity of such compounds as digitoxin where the fatal dose is considered around 0.5 mg./Kg. or phenobarbital, fatal dosage around 100 mg./kg.(2) the toxicity of this compound is relatively low. However, with a drug such as chlorpromazine where 1,000 mg./Kg. have been ingested in a suicidal attempt with complete recovery by the patient(3), this drug would appear to be relatively more toxic. The dosage levels which have been used in animals to elucidate the pharmacodynamics of this drug have been of the order 1-10 mg./Kg.(4). The usual therapeutic dose is of the order 0.3-0.5 mg./Kg.

Imipramine is known to produce convulsant spikes in the amygdala and hippocampus of rabbits at dosages of 30-50 mg./Kg. Although, at lower dosages (2.5-10 mg./Kg.) the drug dampens the EEG arousal pattern produced by sciatic nerve stimulation(8). It is thus easy to under-

² Michon, *et al.*(1), reported a suicide in a young French woman who ingested 150-25 mg. tablets. This amount of the drug in an adult represents considerably less per unit of weight than in this patient. However, their patient died 3 1/2 hours after ingestion.

stand how the large dosage ingested by this patient resulted in generalized seizures which probably originated in the rhinencephalic structures noted above. In this patient the grand mal seizures were seemingly fairly easily and rapidly controlled by I.V. Na Amytal.

It is uncertain as to whether the apnea was secondary to the sodium amytal, although the dosage given was quite small. However, the possibility of the amytal potentiating the possible depressant effect of imipramine on the respiratory center is a possibility. There is no question that the immediate intubation and artificial respiration were life-saving procedures in this patient.

It was the consensus of opinion that the cardiac effects noted were peripheral ones involving the conduction mechanisms within the cardiac musculature. It was agreed that central effects of drugs primarily alter cardiac rate but that only peripheral effects on the conduction mechanism of the heart could produce the conduction defect that was observed in this patient. Michon also reported cardiac conduction defects in the fatal case referred to above.

Cardiac tissue apparently has an affinity for imipramine. Häfliger(5), reporting on the differential distribution of the drug in the tissues of rabbits following intravenous injection, found the concentration to be highest in kidney, brain, heart, muscle, body fat, liver, and plasma in that order.

Many compounds are known to produce similar nonspecific EKG changes, *viz.*, digitalis, quinidine, potassium in excess, "Le-

vophed," *etc.* It is of interest that I.V. "Levophed" (1-norepinephrine) has been known to produce a similar, though transient, EKG picture. Imipramine is thought to produce its effect in the central nervous system by "blockage" of both serotonin and norepinephrine. The brain levels of both these compounds are increased by imipramine administration(6, 7). Increasing blood levels of norepinephrine via its release from sites in the nervous system by imipramine might possibly explain this conduction defect, or via a more direct toxic effect of the drug or, perhaps the cardiac effect is totally unrelated to these compounds. More work is indicated to elucidate the mechanism of the production of the conduction defect within the heart that was observed with intoxication by this drug.

A CASE OF PSYCHOSIS PRECIPITATED BY CONFINEMENT IN LONG DISTANCE TRAVEL BY TRAIN

HARBHAJAN SINGH, M.D.¹

Since World War II there has been an increased interest in psychoses precipitated by isolation and prolonged confinement. With the advent of the space age, where men will be subjected to extensive periods of isolation both spatially and temporally, this condition takes on added importance.

The following is a case report of a psychotic episode precipitated by a 48 hour railway coach ride.

Case Report : A 64-year-old white male patient was admitted to the Emergency Department of the Ottawa Civic Hospital with lacerations of his face and various other parts of his body on August 14, 1960. Physical examination

¹ Ottawa Civic Hospital, Ottawa, Can.

revealed no serious injuries of an internal nature. This man had leaped from an Ottawa-bound train, travelling at about 45 miles per hour, shortly before the train reached Ottawa. While still in the Emergency Department the patient was given a psychiatric evaluation and was followed through during his stay in the hospital.

According to the history obtained from the patient and his wife, they both had emigrated from England in 1926 and had settled in Saskatoon, Saskatchewan. About 4 years ago the patient's wife started losing her vision and gradually became completely blind. The patient retired from his job in order to care for his wife. Since both he and his wife were drawing old-age pensions, they decided it would be worthwhile to return to England where they could be close to their families and where, they felt, the wife would receive more abundant care. The patient and his wife left Regina, Saskatchewan, by railway coach, on their way to Montreal where they were to board a boat for England. Travelling by coach, and because of his wife's blindness, the patient was very restricted in his ambulations. He was unable to take her to the dining car or to walk in the train, having to minister to his wife even to the extent of helping her to use the bathroom facilities. Their diet during the train ride consisted entirely of sandwiches and coffee.

The patient's wife had experienced a nervous breakdown about 10 years previously which required hospitalization. On the train she became somewhat insecure, kept holding his hand, and wouldn't even permit him to get up from the seat. On the second day of travel the

patient began to show signs of restlessness. The following day, he manifested a belief that the fellow passengers were accusing him of spreading venereal disease, especially through his wife. This delusion was tied in with his role as nurse-maid to his wife and with his helping her in toileting. He suspected the fellow passengers of taking flash photographs of him, and of tape-recording all his conversations, with the aim of getting him off the train (because of his V.D.). He also believed that if he did not get off the train one of the leaders of the group would stab and kill him. This group, he believed, was being paid to get rid of him by a secret persecuting agency.

While in the Emergency Department the patient stated that he had jumped from the train, not to kill himself, but to escape his persecutors. He was coherent, relevant, and well oriented in all spheres and his conversation, other than in the circumscribed delusional area, was quite rational. Evidence of memory impairment could not be elicited, nor was there any history of previous mental disturbance. Physical examination and laboratory findings were essentially negative.

The patient was put on 50 mg. of chlorpromazine t.i.d. He calmed down considerably under this medication, relaxed, and became very pleasant and co-operative. However, he retained his delusional thoughts concerning the train incident throughout his stay in the hospital and was discharged 9 days after admission as improved.

The patient, still on chlorpromazine, was sent to England by air travel and was advised to seek psychiatric care there.

AORTIC DACRON GRAFT SURGERY AND ELECTROSHOCK: REPORT OF A CASE

A. H. CHAPMAN, M.D.¹

In recent years, as new types of vascular surgery have been developed, the clinical problem will arise occasionally as to how a patient who has undergone such surgery will later tolerate electroshock if he should need it(1). I am here reporting successful electroshock therapy in a patient who had had surgical removal of the terminal aorta and the proximal parts of both common

iliac arteries with replacement by a dacron prosthesis.

The first report of electroshock treatment in a patient with an aortic graft was made by Monke in 1952(2). Weatherly and Villien in 1958 reported 8 electroshock treatments without complication in a depressed patient who had previously had a homograft replacement in his thoracic aorta after removal of an arteriosclerotic aneurysm(3). Greenbank in 1958 reported a patient who had previously had homograft replacement

¹ Dept. of Psychiatry, Kansas University School of Medicine, Kansas City, Kans., and St. Mary's Hospital, Kansas City, Mo.

of the terminal aorta and its bifurcation, to whom 10 electroshock treatments were given without difficulty(4).

Case Report.—This 45-year-old married housewife developed pain, burning and numbness in both feet and legs in early 1958. She had increasing cyanosis and cramping in her legs and some low back pain. These symptoms were aggravated by exercise, and relieved by elevation of the feet and legs. On examination in early 1959 she was found to have cyanosis on dependency in both legs and diminished femoral pulses; no pulsations could be felt in her feet.

In May of 1959 the patient had surgical resection of the terminal 8 cm. of her aorta, and removal of the aortic bifurcation and the proximal several centimeters of both common iliac arteries. A crimped dacron prosthetic graft was sutured into place by end to end anastomosis to the terminal aorta and the common iliac artery on each side. A bilateral lumbar sympathectomy was performed from L-2 to over the pelvic brim at the same time.

The patient's post-operative course was satisfactory, and she has since remained free of vascular symptomatology. Pathological examination of the removed section of aorta and common iliac arteries showed obliterating arteriosclerosis.

Beginning in the spring of 1960 the patient became progressively depressed and agitated. She slept poorly, felt people did not like her and cried a good deal. She felt worthless and guilty, and had some suicidal thoughts. When seen in consultation in November of 1960 she presented the picture of a marked agitated depression. A trial on imipramine anti-depressant medication administered by her family doctor had not been helpful. Her history revealed that in 1950 she had had a similar depressive

illness which responded well to electroshock therapy, and since then she had remained free of psychiatric difficulty until the beginning of her present depression.

In hospital, following consultation with the surgeon who had performed the vascular surgery, it was decided to institute a course of electroshock treatment, and 8 of these, with induction of a convulsion in each, were given in the usual manner. Each electroshock treatment was preceded by the intravenous administration of 0.2 gm. of sodium pentothal and 40 mg. of succinylcholine chloride; 0.6 mg. of atropine was also given before each treatment. The patient also received 100 mg. of imipramine each day.

She recovered from her depression, and at time of discharge from the hospital was a cheerful, active and gregarious person. No complications or abnormalities occurred during the electroshock treatment. The patient has been seen in follow-up visits and she continues to do well.

Vascular grafts can rupture at a later date, though the types of defects or stress which lead to rupture are not known(5). This complication following electroshock treatment in such patients has not been reported.

IMIPRAMINE HYDROCHLORIDE¹ IN THE TREATMENT OF NARCOLEPSY—A CASE REPORT

ROBERT E. PECK, M.D.²

Narcolepsy is a condition rarely seen by the average physician. The present case is reported because it responded to imipramine in what appears to be a specific way.

It is hoped that other practitioners may wish to test this drug on their own cases.

The patient is a 25-year-old white male, somewhat overweight, but not otherwise abnormal physically or neurologically. An examining psychologist described him as having oral-dependent characteristics but not definitely

¹ Tofranil, Geigy Pharmaceuticals, Ardsley, N. Y.

² Clinical Director of Psychiatry, Meadowbrook Hospital, East Meadow, N. Y.

neurotic. He had suffered since the age of 15 from spells of uncontrollable sleepiness preceded by an aura of tinnitus, floating, or numbness, and waking spontaneously after 3 to 10 minutes refreshed. There were a few instances of automatisms during the attacks and several episodes of hallucinations after. Attacks occurred at least once a day. There were also frequent attacks of cataplexy in which he would suddenly become weak and collapse helplessly. These were precipitated by laughing and occurred earlier than the narcolepsy; he remembers his friends teasing him as a boy in order to precipitate them.

In spite of his disability he had developed fairly normally and made a good adjustment. He had served in the army and his condition had gone undetected until he himself brought it to the attention of the authorities in order to avoid a detail wherein he would have had to drive a number of men home from a dance. He was hospitalized briefly, received an EEG which was normal, and discharged from the hospital. Presumably his condition was not considered serious as he received no change in duty status and did not receive a medical discharge from the army. He entered the nightclub business with his brother and has been moderately successful and enjoys his work. He is quite ambitious. He is happily married to a registered nurse and adjusts normally sexually.

He had previously been treated successively with amphetamine 20 mg. per day and methylphenidate up to 80 mg. per day. He improved temporarily on each, but always developed a tolerance to these drugs. He had also been treated unsuccessfully for a time by a psychologist with psychotherapy.

When he first came to me a year ago I treated him with psychotherapy but there was little anxiety or pathology to work with and this proved unrewarding. I then attempted hypnosis(2), but, though cooperative, he was not a good subject and I was

unsuccessful. Knowing that the usual sympathicomimetics were only of temporary help, I suggested to him that we try some of the antidepressants that had recently appeared. Accordingly he was placed on imipramine in gradually increasing doses up to 150 mg. a day. Within 2 weeks he was completely free of narcolepsy and remained so. He became much freer and would venture things he wouldn't have previously such as long auto drives. He has never shown any tendency to develop a tolerance to imipramine as he had to the other drugs. It must be emphasized however that his attacks of cataplexy have been completely untouched by the imipramine.

After several months of relief from imipramine, I arranged for his wife to substitute placebos in place of the pills. After a week the attacks recurred and continued until he went back to the regular drug. The experiment was repeated again later with similar results. Last April he was placed on phenacemide(1) and stayed on this 2 weeks, but his narcolepsy returned and he discontinued it. He then dropped out of treatment and treated himself. He stayed on 50 mg. imipramine a day and was symptom-free. During the month of May he had no narcoleptic attacks and took no medication. In June they recurred and he went back on 50 mg. for a week. He has had neither pills nor attacks since. At my request he returned for a follow-up visit, he is doing and feeling well and is quite happy about the treatment.

ACUTE TOXIC PSYCHOSIS CONCURRENT WITH PHENOTHIAZINE THERAPY

ALBERT W. LANG, M.D., AND ROBERT A. MOORE, M.D.¹

Although the literature is replete with reports of various untoward reactions to

phenothiazine therapy, including neurotoxic manifestations, there are few reports of the development of an acute toxic psychosis. Kinross-Wright(1) and Ayd(2) report on

¹ Department of Psychiatry, University of Michigan Medical School, Ann Arbor, Mich.

chronic psychotic patients receiving large doses of chlorpromazine. May(3) describes two cases of catatonic-like states in acutely schizophrenic patients, one receiving small doses of chlorpromazine and prochlorperazine, and the other receiving large dosages of prochlorperazine. Berry(4) observed two cases of cataleptoid states in children associated with perphenazine therapy.

The patient is a 27-year-old white married office clerk, father of two children, admitted to the Veterans' Readjustment Center, of the University of Michigan Medical Center, complaining of anxiety, dizziness, palpitations, and the fear that he would be unable to breathe or that his heart would stop. These symptoms had appeared 3 years previously after the birth of his first child and following the observation of a heart attack in an elderly man. His complaints were intermittent but progressively disabling prior to admission.

On admission the patient was tense, somatically preoccupied, lacking in insight, but did not reveal overt psychotic or organic symptoms. On psychological tests, early signs of ego disorganization were seen in an overall picture of a passive-dependent personality. Physical and neurological examinations and laboratory studies were negative.

After 23 days in the hospital with psychotherapy thrice weekly, it was found the patient had been unable to participate beyond repetition of concrete fact of his life. At staff conference an opinion of incipient schizophrenia was given. The patient was then started on chlorpromazine, 25 mgm. q.i.d.

Following 3 doses (total, 75 mgm.) he was in panic, complaining of palpitations; pulse was 170 per minute. He subsequently complained of "feeling like an empty shell, floating around in the air." Following a night's sleep, induced by secobarbital 200 mgm. the chlorpromazine was increased to 50 mgm. q.i.d. After 2 doses, the patient experienced auditory hallucinations which he felt emanated from 2 small men standing on his chest. During the next 2 days, he showed progressive deterioration with increasing drowsiness, dysarthria, dysphagia and weakness. Chlorpromazine was discontinued and trifluoperazine 2 mgm. q.i.d. was commenced. After 2 more days of continued confusion and panic, the patient disappeared from the hospital. Upon return 8 hours later he ex-

pressed delusions, complained of depersonalization and auditory hallucinations and showed a marked increase in dysarthria, dysphagia, diplopia, ataxia and coarse tremors. He again absconded from the hospital before further evaluation was possible. He had received 725 mgm. of chlorpromazine over a 5-day period and 22 mgm. of trifluoperazine during an additional 3 days.

He was admitted to a nearby general hospital(5) where treatment included intravenous Amigen in 5% glucose, multivitamins, potassium, promethazine 25 mgm. the first night for sleep, and dilantin and phenobarbital for his severe tremors. Recovery was complete in 7 days and he was able to return to work.

The patient was seen briefly by one of the authors (AWL) 6 days after leaving the general hospital and 11 days after leaving Veterans' Readjustment Center. He was somewhat tense, anxious to collect his belongings, rather critical of his treatment, but revealed no psychotic or organic symptoms beyond a patchy amnesia for part of the psychotic episode. He was unwilling to submit to further examination.

This case history reports development of an acute psychotic episode a day after chlorpromazine therapy was begun at 25 mgm. q.i.d. Although there was suggestion of an incipient schizophrenic process before this, the acute psychotic episode was more clearly toxic with definite neurological findings. This opinion was strengthened by the loss of symptoms after cessation of phenothiazine therapy. We believe that chlorpromazine was the responsible agent rather than the trifluoperazine. One 25 mgm. dose of promethazine did not cause any return of symptoms. This case differs from others reported as this patient was not overtly psychotic previous to phenothiazine therapy and received relatively small dosage.

HISTORICAL NOTES

PREDECESSORS OF MORTON PRINCE'S DISSOCIATION CONCEPT

ERNEST HARMS¹

In his short biography of him, Merrill Moore justifiably designates Morton Prince as America's most highly reputed psychiatrist. This reputation rests mainly on the wide acknowledgment accorded Prince's studies on the dissociation of personality or double personality and consciousness. This work placed Prince next to Kraepelin and Bleuler in laying the ground for the study of schizophrenia, the somatological work of which during the past 50 years has hardly advanced beyond what was accomplished by these 3 men.

The main point of Prince's study was that the usual normal unified consciousness of the personality can "disintegrate so that a second personality may come into being, designatable as 'double,'" and that this second consciousness may alternate with the first. This falling into parts of the unified consciousness is a pathology. Prince's merit is considered to lie in the fact that he was the first to describe this aspect of the somatology of schizophrenia, or dementia praecox.

The historian who turns over the literature of the past carefully, frequently finds that such "firsts" have predecessors who in full or nuclear form presented the facts now considered "new" or who speculated about them. Of those who anticipated Prince in the area of the so-called "double-consciousness" the most impressive were two British physicians of the 1840's, Sir Henry Holland and Dr. Arthur Ladbrooke Wigan.

Holland, a fashionable court physician of his time, presented, in his *Medical Notes and Reflections* (1842), which appeared in many editions, a chapter on "The Brain as a Double Organ," in which he expressed vexation about the functioning of the two cerebral hemispheres. He speculated that "aberrations of the mind called insanity may be due to incongruous action of this double structure. In consequence there could be

two states of consciousness side by side or following one another according to changes of conditions." He pointed to cases of hysteria in which there have appeared "two minds" and "a sort of double dealing with oneself." He considered the term "double consciousness" for such states permissible, and he referred to a case reported by Herbert Mayo in his *Outlines of Human Physiology* (1837) in which a case history was presented that is almost identical with Morton Prince's "Miss Beauchamp," a girl who experienced "fits" lasting up to 3 days, from which she "awakened" as a different person, not remembering the previous state.

A more impressive presentation of earlier observations of "dual consciousness" came from a contemporary and countryman of Holland, Arthur Ladbrooke Wigan. History has treated this important man rather strangely. Although referred to in contemporary literature as ingenious and celebrated, nothing about his life has come down to us, except the date of his death, December 7, 1847. Dr. Wigan wrote 2 books, several pamphlets, and numerous letters to *The Lancet*. His major book, which was much discussed for several years a century ago, was entitled *Duality of the Mind* (1844). In it he tried to prove the thesis that the two hemispheres of the brain are two completely separate organs functioning independently side by side, whose collaborating function resemble somewhat that of the eyes, giving self-control and security to man's mental functioning. Most mental diseases, Dr. Wigan believed, resulted from the non-functioning of one or both of the cerebral hemispheres or their malfunctioning or contradictory activity. Wigan elaborated this idea for most of the neurology and neuropsychiatry of his day. In some of his keen speculations he reached far beyond his time and into the basic concepts of the present century. He had astonishing foresight of later insights into the constitution of the nervous system. He says :

¹ 158 East 95th Street, New York City.

The right brain (i.e., the right hemisphere) has no command over the right leg nor the left brain (left hemisphere) over the left leg; whenever the right brain is paralyzed, there is no power whatsoever to move the left limb, yet the left brain moves the right as well as ever—consequently, the brains (the right and the left hemispheres) are capable of independent action . . . I hope that I have proved a great many things besides the alternate influence of the two brains on muscular motion.

Among Wigan's amazing observations is the first actual inductive description of the schizophrenic thought process, which he presents in 4 pages, and from which I quote a brief passage: "Bring the tea—tea comes from China—wall of China—wall, mur, mur-aille—difference in French—French habits—habit, coat, long-tailed coat for soldiers—jackets . . ." This certainly seems identical with Bleuler's "first" descriptions.

Probably the most impressive reach of Wigan's thought into 20th century psychiatry is his anticipation of Prince's dissociation concept, shown in the following passage:

We have examples of persons who from some hitherto unexplained cause, fall suddenly into, and remain for a time, in a state of existence resembling somnambulism, from which, after many hours, they gradually awake—having no recollection of anything that has occurred in the preceding state—although, during its continuance they had read, written and conversed, and done many other acts implying an exercise, however limited, of the understanding . . . They now pursue their ordinary business and avocations in the usual manner, perhaps for weeks, when suddenly the somnambulist

state recurs, during which, all that had happened in the previous attack comes vividly before them, and they remember it as perfectly as if that disordered state were the regular habitual mode of existence of the individual—the healthy state and its events being now as entirely forgotten, as were the disordered ones during the healthy state. Thus it passes on for many months, or even years. This is what is called *double consciousness*—the person being in a manner 2 individuals, as far as sensation and sense of personal identity are concerned.

Besides the dual state which Wigan designated as somnambulist, he further described one in which a falling into an infantile state alternated with adult consciousness, a form seldom reported but probably not too rare in our time.

There are of course basic divergences between the theoretical concepts that Dr. Wigan applied to his cases and what modern academic neurology and psychiatry cherishes. There are naturally also basic differences in theories and conclusions as between Wigan and Morton Prince. This is to be expected. The astonishing thing is the manner in which the facts were observed and presented as early as prior to the mid 1800's, and this certainly deserves to be lifted out of the forgotten past and brought to historical acknowledgment. The historian may of course also be puzzled by the fact that the life and work of such an outstanding scientist as Arthur Ladbroke Wigan has been lost in the past, but this is a riddle we shall hardly be able to solve.

THE PRESIDENT'S PAGE

Our Editor has asked if, before my term of office expires, I would comment on what has seemed of greatest significance to me in the past year.

Manifestly, in a fleeting year, the President primarily presides over dynamic movements that were set in motion long before he took office and which will remain in motion long after he leaves. He may play some part in tilting a few of these movements in slightly different directions, or perhaps add an ingredient that changes them slightly qualitatively. He may even set a new project or two in motion, but how successfully he will not know until long after his term is over.

Nearly every President, however, has at least one or two special concerns that he seeks to advance as best he can while in office. One of mine has been to find ways of assuring an ever-more vigorous and effective functioning of APA Committees; and to this end, a few ideas have been set in motion that one may hope will develop further under my successors.

There are at least eight essential ingredients characteristic of effective committee functioning.

First, there must be an efficient mechanism for appointing committee members. In many professional associations, including our own, such appointments are made by the President. This is a function which requires serious thought, since the number of committee vacancies which occur each year are limited and qualified members are many. In appointing a committee member, any President will ask such questions as these: How knowledgeable is he in the area of the committee's concern? How much interest has he demonstrated in the Association's affairs? Has he advanced to Fellowship status? If he is a relatively new member, does he show promise which should be developed through committee appointment? Does he offer special insights or points of view that will enrich the representativeness of the committee? Does he work well with a group? Sometimes it is important to ask where he comes from,

since geographical representation must also be considered. Naturally, in making appointments, a President will consult with as many people as he can. In recent years, since the advent of the District Branches, they have been asked for recommendations. Perhaps there is a better way of selecting committee members, but, if so, no one has come up with it.

Second, every committee must have a reasonably well defined mission and the morale to carry it out. That these qualities are abundantly present in APA committees has been demonstrated time and again. This year, for example, all committees were asked to define their mission and none had any trouble in doing so.

Third, committees must have sufficient funds to enable them to meet as often as is necessary to accomplish this mission, and to bring consultants to their meetings if need be. As matters now stand, the budget will allow committees to meet regularly only once a year with expenses paid, and rarely are funds available for consultants. It will be a productive day when funds will be available to support an adequate number of meetings to enable the committees to do what they should do and are so capable of doing.

Fourth, communication must be "easy" among the different committees on matters of mutual or overlapping concern and between the committees and the Council. It is in this area that perhaps our most troublesome problems arise. Inter-communication among the committees has been tremendously facilitated over recent years by having all committees meet simultaneously in the fall, and by placing the three Coordinating Chairmen in a position to be aware of overlapping interests and to represent the committees before the Council.

The truly troublesome problem is the lack of time that Council has available at its meetings to devote to committee concerns. With each passing year the agendas of Council grow more and more burdensome, and all too often committee reports and recommendations cannot be given the

thoughtful consideration they deserve. Two suggestions have been made this year which may contribute to the problem.

I have suggested that Council appoint a "Reference Committee" comprising the three Coordinating Chairmen and, perhaps, one or two others, with the Medical Director and others in the Central Office serving them in a staff capacity. This Reference Committee would, in effect, serve as a kind of screening agency for the Council. That is, it would meet in advance of and be prepared to advise the Council on referring various agenda items to the proper committees concerned and to recommend appropriate action on matters referred to it by Council. A second suggestion has come from the Medical Director, that Council add an extra day to its traditional two-day meetings, a day that would be devoted entirely to the consideration of committee affairs. It is to be hoped that both of these suggestions will be given every consideration.

Fifth, there must be adequate professional and technical staff support for the entire committee structure. Under professional direction, the Central Office, as our communications center, can keep committees informed of developments that concern them. It can often do some of their spade work, such as bibliographical research or the preparation of background material. It can apprise a committee of overlapping interests with other committees, and help to avoid duplication of effort. It can inform committees of policies and procedures. It can render them all manner of staff support such as typing, mailing, mimeographing, printing, fund raising, arranging for meetings, and the many other chores entailed in the production of reports. Under this heading, great headway has been made this year by the Medical Director who has streamlined administrative procedures in the Central Office to render more of this kind of support to the Committees. Especially auspicious is the addition of an Assistant Medical Director to the staff who, with adequate secretarial support, will devote much of his time to meeting the administrative needs of the committees.

Sixth, there must be a facility for the publication of worthwhile committee reports. This, too, is in part a budget problem.

Printing, editorial processing and distribution is expensive. The Central Office, within budget limitations, has done the best it could to publish as many committee documents as possible. But it is one thing to publish a document which has sufficient audience appeal to pay for itself through sales, and quite another thing to publish one which, while equally worthwhile, has a much smaller sales potential. Manifestly, there is little incentive to produce a document if it cannot be published and distributed. Here again, more thought must be given to how the publication of committee reports may be financed.

Seven, there needs to be a training ground for future committee members. The most promising source of future national committee members lies in the District Branches which tend to form committees along lines that parallel the national structure. Just as Presidents consult with Branch officers on outstanding candidates for APA Committee appointments, the development of closer working relationships between the national committees and their Branch counterparts will bring to light many a promising candidate. Moreover, the Council has, this year, approved the formation of "Task Forces" to accomplish certain special projects that cannot be reasonably assigned to an existing committee in addition to its present concerns. Such Task Forces would be directed by a committee as a rule, but would rely on other personnel, including, on occasion, persons from outside the Association, to accomplish its assignment. These Task Forces may also elicit candidates for future committee work.

The *eighth* requirement is more elusive. It has to do with the attitude of the membership at large about the leadership role that the Association is to play. Such a role is most clearly implicit in the stated objectives of the Association which cannot be repeated too often:—to advance standards to treatment and care for the mentally ill; to make psychiatric services available to all who need them; to further psychiatric education and research; and to extend psychiatric knowledge to other professions and to the public generally, working toward the common goal—the ultimate prevention of mental illness.

It is in this leadership context that I have recommended that the Association should have more "opinions" about matters that are of fundamental concern to the profession and to which the profession can make a *special* contribution. Using the word loosely, such "opinions" may take the form of a precautionary statement on the irresponsible use of psychoactive drugs or hypnosis, a set of propositions about the best methods of educating family physicians in psychiatry, a stand on ways and means of overcoming the manpower shortage, or on any of many other pertinent questions about which we are daily asked as the organization logically held to be the authority in our field.

Such opinions must be formulated not with the thought that they represent the precise views of every member of the Association (manifestly impossible), but rather as thoughtful judgments reflective of pre-

dominant trends in current professional thinking. They should be published in the spirit of providing helpful information and guidance for all concerned, rather than as "official edicts."

If such opinions are framed in the committees, and brought to a fine polish in the machinery of inter-committee deliberations and final clearance through the Council, one may have confidence that they will reflect predominant thought within the progression.

So much for a major concern of your President this past year. Next month the mantle of office will fall on the sturdy shoulders of Dr. Walter Barton. All success to him; he richly merits the enthusiastic support of each of us.

R. H. FELIX, M.D.,
President

CORRESPONDENCE

CRITICISM OF REVISED PSYCHOPHARMACOLOGICAL SURVEY

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : A useful survey of psychopharmacological agents was recently published under the head of Clinical Notes in your *Journal*.¹ There are, however, a few criticisms which I would make.

1. Chlorpromazine is given an effectuality rating of "Good-1" whereas triflupromazine is given a rating of "Fair-2." Yet triflupromazine is described as being more potent and perhaps more rapid-acting than chlorpromazine. This seems to be contradictory. 2. None of the other phenothiazine drugs are given an effectuality rating better than 2 whereas it might be the experience

of the majority of psychiatrists that some of the newer phenothiazines are as effective as or are more effective than chlorpromazine. 3. The anti-psychotic action of some of the major tranquilizers is not limited to a suppression of hallucinations and delusions. Other effects such as improvement in the patient's contact with reality are also important and might have been mentioned. 4. To include toxicity and side-effects under one scale is apt to be misleading. It would have been better to have separate scales for dangerous toxic reactions and comparatively harmless side-effects. 5. The tendency for chlorpromazine like *Rauwolfia* to increase depression might have been mentioned.

R. B. Davis, M. B., D.P.M.,
Kishore Nursing Home,
Ranchi, India.

¹ James P. Cattell, M.D., and Sidney Malitz, M. D. : *Am. J. Psychiat.*, 117 : 449, 1960.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : We appreciate Dr. Davis' interest in the drug survey to which he refers and comment on his criticisms in the order he has presented them. 1. The "potency" of a drug usually connotes the dosage range in which therapeutic effect or physiological change are clinically observable. Triflupromazine is thus more "potent" in that the dosage range is 10-30 mg. t.i.d.—in contrast to chlorpromazine : 25-150 mg. q.i.d. Our experience, and that of our associates, has led us to conclude that chlorpromazine is the more effectual drug. 2. The experiences of the majority of psychiatrists about the effectuality of some of the newer phenothiazine derivatives have not been reported. Chlorpromazine has been administered to more patients for longer periods of time with definite benefit, according to a significant minority of psychiatrists' reports. We hope that some of the more recent derivatives will prove to be safer and more effectual and are seeking evidence to demonstrate this. 3. A brief survey of this type can-

not include a comprehensive list of all psychotic symptoms and how they are affected by each drug. The scientific literature and the pharmaceutical house advertisements devote much attention to such issues. In preparing this survey, we wished to provide a concise evaluation of the effectuality and side effects of these psychopharmacological agents, on the basis of our experience and the literature, for ready reference for anyone who might be interested. 4. We agree that there would be merit in listing toxic reactions and side reactions separately, perhaps with different rating systems. This would certainly be in order were this simple survey to be expanded into a comprehensive monograph, as would the inclusion of many other topics including those mentioned under 3. 5. Depression is mentioned as a side effect of chlorpromazine administration in column 2, line 5 of the survey.

BOOK REVIEWS AND REVIEWERS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : In the *American Journal of Psychiatry*, vol. 117, Aug., 1960, is a review signed by Hans A. Illing, Ph.D., Los Angeles, California, which calls for a reply. The review is of *Das Menschenbild der Seelenheilkunde* by Viktor E. Frankl (Stuttgart : Hippokrates Verlag, 1959).

No reviewer is required to agree with the author he reviews, but surely we may expect him to understand the author and to quote him accurately. Otherwise confusion is the only outcome. Dr. Illing cites only 2 items from Frankl's book, which appear on pages 108 and 109. Each of these citations is erroneous. The first is quoted from Ludwig Zeise, but made to read as if from Frankl. Taken out of context the implication

is a total rejection of Freud, but elsewhere in the book Frankl refers to Freud as the great pioneer of whose genius we are all convinced.

The second error is equally misleading as Dr. Illing takes parts of a sentence to mean precisely the opposite of what Frankl actually says. Instead of saying "the mass neuroses of mankind cannot be resolved," as the reviewer has it, Frankl says that "the collective neuroses of mankind cannot be resolved unless freedom and responsibility are appealed to."

I hope that you will bring these needed corrections to the attention of your readers.

Paul E. Johnson,
Professor, Boston University,
Boston, Mass.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : Professor Johnson remarks aptly that my quotation "quoted from Ludwig Zeise" was "made to read as if from Frankl." This was not intended by me, nor did I wish to insinuate that Frankl "rejects Freud." Likewise, my second quotation was taken "out of context," although it can be argued that my omission of the last portion of my quotation "unless freedom and responsibility are appealed to," was not done so inadvertently since I believe Frankl holds that freedom and responsibility are appealed to *in vain*.

In my attempts to present to the English-speaking psychiatrist all-too-short reviews of current German Psychiatria, I may sometimes fall short of avoiding errors, particularly in regard to translations, since the matter of semantics is ever present, I hope Professor Johnson will bear with me, especially since I have given Dr. Frankl credit on many other occasions in the pages of this *Journal*, with particular reference to Frankl's co-editorship of the *Handbuch der Neurosenlehre und Psychotherapie*.

Hans A. Illing, Ph.D.

VERITAS

The true means the verified and means nothing else.

—JOHN DEWEY

OFFICIAL REPORTS

REPORT OF THE NOMINATING COMMITTEE

The following candidates have been nominated for election for the year 1961-1962.

President-Elect : S. H. Hardin Branch, Salt Lake City, Utah.

Vice-President : Henry Brosin, Pittsburgh, Pa.

Vice-President : Titus Harris, Galveston, Tex.

Secretary : Harvey Tomkins, New York, N. Y.

Treasurer : Addison M. Duval, Jefferson City, Mo.

Councillors (3 to be elected from 6 nominees) :

Robert Garber, Belle Mead, N. J.

Cecil Wittson, Omaha, Neb.

Francis J. O'Neill, Central Islip, N. Y.

Zigmond Lebensohn, Washington, D. C.

Alfred Auerbach, San Francisco, Calif.

Herbert S. Ripley, Jr., Seattle, Wash.

NO HOLY WARS FOR THEM

States strong enough to do good are but few,
Their number would seem limited to three.
Good is a thing that they the great can do,
But puny little states can only be.
And being good for these means standing by
To watch a war in nominal alliance,
And when it's over watch the world's supply
Get parceled out among the winning giants.
God, have you taken cognizance of this ?
And what on this is your divine position ?
Most nations like the Cuban and the Swiss
Can never hope to wage a Global Mission.
No Holy Wars for them. The most the small
Can ever give us is a nuisance brawl.

—ROBERT FROST

MYSTICISM VS. REASON

I have always instinctively dreaded mysticism (although fascinated by it) as endangering the light of reason—a poor light, nearly always smoking, and often stinking, but yet all we have to let us go forward a few feet in a century toward a positive, materially better world, opening out greater possibilities of genuine and not merely ecstatically illusive states of euphoria.

—BERNARD BERENSEN

NEWS AND NOTES

DES MOINES CHILD GUIDANCE CENTER SALARY SURVEY.—Now available is the 1960 Salary Survey prepared by the Des Moines Child Guidance Center. This is a survey of salaries offered to various professions in mental health facilities. These facilities were selected on the basis of staff including at least one psychiatrist, one clinical psychologist, and one psychiatric social worker. In 1958, survey questionnaires were mailed to all outpatient and inpatient health facilities listed in available directories as having a staff including at least one full-time person in each of the 3 professions. The 1960 questionnaire is essentially identical with that of 1958, the information included being obtained from 546 organizations.

This booklet is available from the Des Moines Child Guidance Center, 1206 Pleasant Street, Des Moines 14, Iowa, at 35 cents per copy, or 25 cents for 10 or more copies.

AMERICAN ASSOCIATION OF MARRIAGE COUNSELORS.—The annual meeting of the National Council on Family Relations will be held August 23-25, 1961, at the University of Utah, Salt Lake City.

For further information write Ruth Jewson, Executive Secretary, National Council on Family Relations, 1219 University Ave. S.E., Minneapolis 14, Minn.

THIRD WORLD CONGRESS OF PSYCHIATRY.—Among the features of the 3rd World Congress to be held in Montreal, Canada, June 4-10, 1961, will be a panel, chaired by Dr. Robert H. Felix, comprising authorities from countries in which national psychiatric programs have been particularly well developed. This panel will deal with problems of organizing mental hospitals, psychiatric divisions in general hospitals and departments of psychiatry in universities, community health services and clinics, school and child guidance clinics, industrial mental health clinics, research laboratories and other facilities. A series of advance sessions will be chaired by Professor Jean Delay of Paris.

The 3rd World Congress, sponsored by the Canadian Psychiatric Association and McGill University, will provide the first opportunity since 1950, when the first Congress was held in Paris, for psychiatrists from all over the world to meet together. It is expected to attract over 3,000 psychiatrists from 62 nations. There will be 9 plenary and 31 major panel discussions during the week. Simultaneous translations will be provided in the 4 official languages of the Congress—English, French, German, and Spanish. More than 400 scientific papers are listed.

Information on registration and travel may be obtained from World Congress of Psychiatry, Allan Memorial Institute, 1025 Pine Ave. W., Montreal 2, Canada.

DAVID C. WILSON LECTURE IN PSYCHIATRY, UNIVERSITY OF VIRGINIA.—The 3rd annual David C. Wilson Lecture will be given by Dr. William B. Terhune at the University of Virginia School of Medicine, Charlottesville, Va., April 21, 1961.

THE FORT LOGAN MENTAL HEALTH CENTER.—This Center had its groundbreaking ceremony Feb. 3. The new hospital, a part of the Colorado State System, will accept its first patients by the end of 1961.

The program planned for the Center envisions an institution which is closely integrated with local mental health clinics, through which patients will come to the hospital and which will also provide after-care and follow-up services. Team members of all professional disciplines will offer intensive treatment to patients, maintain liaison with the local clinics and provide them with professional resources. Training and research programs are also planned for the future.

NEW POSITION OF TRAINING AIDE IN SCHOOLS FOR MENTALLY RETARDED.—Establishment of a new position of training aide in the state schools for the mentally retarded has been announced by Dr. Arthur

W. Pense, Deputy Commissioner of Mental Hygiene (New York State) in charge of the Office of Mental Retardation.

The first group of aides will receive special training at Willowbrook State School (Staten Island) in teaching methods and theory, and practical teaching experience in classrooms there. The first class is expected to open March 13, 1961, and will be conducted by Charles McAllister, Director of Mental Hygiene Education Services.

Qualifications for the position are permanent employment as an attendant with at least 6 month's experience in an institution for the mentally defective, high school graduation or an equivalent diploma, and ability to relate with children and to organize children's activities.

For information call Mrs. Margaret M. Farrar, Albany HObart 2-7511, Ext. 5561.

STATEMENT ON MEDICAL ASSISTANCE FOR THE AGED.—A Statement titled "Medical Assistance for the Aged and Nursing Services in the Home" has been prepared by the U. S. Department of Health, Education, and Welfare in cooperation with the Division of Program Standards and Development, Bureau of Public Assistance, Social Security Administration.

This statement was designed primarily to assist States develop plans for home nursing care under Medical Assistance for the Aged programs. It includes such information as the types of services to be provided, the availability and development of home nursing services, and inter-agency and inter-group relationships.

Single copies of this statement can be obtained from the U. S. Department of Health, Education, and Welfare, Public Health Service—Division of Nursing, Washington 25, D. C.

DOCTORS ROSS AND KAPP HONORED.—The 1960 Franz Alexander Prize of the Chicago Institute for Psychoanalysis was awarded on January 25, 1961, to Dr. W. Donald Ross and Dr. Frederic T. Kapp, Associate Professors of Psychiatry at the University of Cincinnati, for their paper on "A Technique for Self-Analysis of Countertransference."

The paper is part of the long-term examination by the therapists of their own passing emotional responses to the material of hours of psychotherapy. The technique makes use of a study by the analyst of his own visual imagery as he listens to the report of dreams and other psychological material discussed by the patient during an hour of psychotherapy.

RESEARCH TRAINING IN MENTAL HEALTH AT HARVARD.—The Harvard Medical School and the Massachusetts Mental Health Center announce the second year of a post-doctoral training program in mental health research beginning July, 1961. The objective is to provide an intensive research experience in a specific mental health field.

Trainees will be expected to spend most of their time working on a specified research project in one of the participating laboratories—neurophysiology, neuropsychology, biochemistry, psychophysiology, psychopharmacology, sociopsychology, and clinical psychiatry. Stipends of \$6000 for the first year and \$7000 for a desired second year are provided.

For further information write Milton Greenblatt, M.D., Director of the Program, or Elliott G. Mishler, Ph.D., Assistant Director, at 74 Fenwood Road, Boston 15, Mass.

GRADUATE COURSE IN CRIMINOLOGY, UNIVERSITY OF CAMBRIDGE.—The University of Cambridge has established a Graduate Course in Criminology, to be given by the Institute of Criminology, and leading to a diploma beginning in 1961. Each year the course will extend from October to July.

The program will include 105 lectures and 90 seminars dealing with all the major aspects of criminology, criminal law and procedure. Individual work will be required at the seminars.

Instruction will be given by the Wolfson Professor of Criminology, the staff, visiting lecturers, and experts from the Home Office.

Application forms for admission to the course are available from the Secretary, Institute of Criminology, 4 Scroope Terrace, Cambridge, England, and should reach the Secretary by May 15, 1961, for the course commencing in October.

NORTH PACIFIC SOCIETY OF NEUROLOGY AND PSYCHIATRY.—The North Pacific Society in conjunction with the Northwest District Branch of the American Psychiatric Association will hold its annual scientific meeting at Harrison Hot Springs in British Columbia on April 7 and 8, 1961.

Guest speakers will be Dr. David T. Graham, Associate Professor of Medicine at the University of Wisconsin, and Dr. Earl Walker, Professor of Neurosurgery at the Johns Hopkins University.

ASOCIACION PSIQUIATRICA PERUNA.—At the general assembly of this Association, June 2, 1960, the following officers were elected for the biennial period 1960-62: President, Dr. Baltazar Caravedo C.; Vice-President, Dr. Arnaldo Cano; General Secretary, Dr. José Sánchez García; Executive Secretary, Dr. Renato Castro de la Matta; and Treasurer, Dr. Elsa Felipa.

A. E. BENNETT AWARD.—The Society of Biological Psychiatry is offering an annual award made possible by the A. E. Bennett Neuropsychiatric Research Foundation. The award will consist of \$500, part of which is to be used for traveling expenses to the annual meeting. It will preferably be given to a fairly young investigator and not necessarily a member of the Society of Biological Psychiatry, for work recently accomplished and not published. The paper will be read as part of the program of the annual meeting of the Society and will be published with the other papers read at that meeting in the book: **BIOLOGICAL PSYCHIATRY**, Volume IV. The honorarium will be awarded at the annual banquet.

Please submit paper in quadruplicate to Harold E. Himwich, M.D., Chairman, Committee of Award, Galesburg State Research Hospital, Galesburg, Illinois. Deadline for manuscripts is April 30, 1961.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—Certified in Child Psychiatry, February, 1961, were the following:

William B. Beach, Jr., M.D., Sacramento, Calif.
Charles L. Block, M.D., Skokie, Ill.
Robert Gabriel Carlson, M.D., Denver, Col.
Robert M. Counts, M.D., Easton, N. J.
Martin B. Fliegel, M.D., Ann Arbor, Mich.

Charles H. Kramer, M.D., Oak Park, Ill.
Nancy Rollins, M.D., Kansas City, Kan.
Sidney Lee Werkman, A.B., M.D., Washington, D. C.

ACADEMY OF PSYCHOANALYSIS.—The Annual Meeting of the Academy will be held at the La Salle Hotel, Chicago, May 6 and 7, 1961. The theme of this meeting is Psychoanalytic Education. Dr. Frances S. Arkin will deliver the presidential address.

The First Frieda Fromm-Reichmann Award will be presented at the luncheon meeting on May 6 and a citation to Stanley Cobb will be presented at the luncheon meeting, May 7.

Inquiries may be addressed to the Secretary, Dr. Joseph H. Merin, The Academy of Psychoanalysis, 125 East Street, New York 21, N. Y.

THE SANDOR RADO LECTURES.—David M. Levy of New York City will deliver the fifth annual Sandor Rado Lectures at the Columbia University Psychoanalytic Clinic for Training and Research on April 14 and 15 at 9 p.m. and 9 a.m. respectively. His presentations will be entitled "The Incomplete Act."

THE LONDON CONFERENCE ON THE SCIENTIFIC STUDY OF MENTAL DEFICIENCY.—On July 25, 1960, the London Conference on the Scientific Study of Mental Deficiency convened. It was the realization of an objective held for the past 15 years by the officers and members of the Royal Medico-Psychological Association of Great Britain and the American Association on Mental Deficiency. With approximately 700 registrants representing some 40 countries, it was the first international multidisciplinary conference on mental deficiency ever held. Interest of the registrants ranged from that of the parent of a retarded child to that of the highly trained research worker.

It was a conference of highlights. The first was the excellent operational plan developed. Each morning the conference met in plenary session followed by sectional meetings in the afternoon for consideration of special interests relating to the retarded. The excellence of the program itself was another highlight. The scientific papers ranged from reports on highly technical re-

searches in body metabolism and human genetics, medicine, psychology, education, social work, to community planning for the retarded. It was truly comprehensive coverage. This diversity served to sustain a high level of interest and enthusiasm throughout the week.

A special session was held Wednesday, July 27, to consider the formation of a permanent International Association on Mental Deficiency. This was voted unanimously as was a recommendation to plan for a second international conference to be held in the near future. Dr. Alexander Shapiro, consultant psychiatrist to Harpersbury Hospital, St. Albans, Hertfordshire, England, and Mr. Harvey Stevens, Superintendent, Central Wisconsin Colony and Training School, Madison, Wisconsin, were designated provisional co-chairmen to develop the proposed plans.

The cordial receptions arranged by the London County Council and the National Ministry of Health were further highlights of the week. These were added to by the official reception and conference dinner held Thursday evening, July 28. Observing an official British toastmaster in action was a

new and unique experience for many of us from the United States.

Perhaps the most impressive feature of the entire conference was the spirit which prevailed. The cohesive force which dominated the week seemed to stem from the dedication of everyone, regardless of national origins, specialty interests or training background, to find jointly solutions to the stubborn problems presented by the retarded population of the world.

While the American Psychiatric Association was represented by a delegate, and other members also attended, it had no part in the planning of the conference. The Association has had an interest in this area of medicine for many years. It would do well to join forces with the other agencies and organizations supporting international developments in mental retardation.

Proceedings of the Conference are being published and will be available after January 1, 1961.

Reynold A. Jensen, M.D.,
Department of Psychiatry and Neurology,
University of Minnesota Medical School,
Minneapolis 14, Minn.

BOOK REVIEWS

HUMAN DEVELOPMENT: SELECTED READINGS.

Edited by Morris L. and Natali R. Haimowitz. (New York: Thomas Y. Crowell Company, 1960, pp. 799, including Index.)

This is an anthology of 80 passages of different length and import, centered around the broad theme of human development. The editors declare in the preface that, in selecting materials, they were guided by the following questions: "What kind of children do we want? What readings in science, philosophy, or fiction eloquently describe the nature of infants and children? How can this knowledge be applied to help children grow?"

The selected items are grouped into 6 major divisions: goals, infancy, childhood, distorted views, planned intervention, and adolescence. Each division begins with a brief introduction by the editors. The menu varies considerably. Thus, in the first section we find 3 excerpts from the Old Testament, the Sermon on the Mount, articles on the family in the U.S.S.R., in India, and in the Kibbutz, a treatise on virtue (by one of the editors), a discussion of creativity (by both authors), papers on parental discipline, identity and interpersonal competence, relation of child training to subsistence economy, a truly delightful sketch on the custom of French families to take their children to the park, and autobiographic reminiscences of George Bernard Shaw. The section on childhood has, among other chapters, discussions on patterns of child rearing, children's humor, projective devices, reactions to finger paints, children's textbooks, leadership and group life. This gives one an idea of the richness and diversity of the offerings. Throughout the volume, clinical observations and reports of experimental studies are interspersed with literary gems, such as excerpts from Butler's *The Way of All Flesh*, D. H. Lawrence's *Sons and Lovers*, Aldous Huxley's *Brave New World*, Einstein's views on education, and Louis Fischer's account of Mahatma Gandhi's adolescence. Even this sampling fails to give the true flavor of this *Lesebuch*.

I believe that the second and third of the three questions which the editors pose are answered amply, if not consistently. There are many thoughtful and some documented descriptions of the nature of infants and children, healthy and otherwise. There are many chapters (in the section on planned intervention) which deal with efforts at modification of a

variety of difficulties. As for the first question: "What kind of people do we want?" much still depends on who does the wanting. The contemporary adult generation is sorely mixed up about its own status and, I fear, transmits its perplexities to child rearing which parents themselves and many experts have managed to deprive of the simple, naïve enjoyment, substituting for this a meshwork of somber rules and regulations.

Possession of this book will reward the owner with the opportunity for many hours of instructive, thought-provoking, and in many instances aesthetically entertaining reading.

L.K.

THE ROOTS OF CRIME. By Edward Glover.

(New York: International Universities Press, Inc., pp. 422. \$7.50.)

This volume consists of studies on crime carried out over a period of 37 years. The various papers, some previously published, some new, are arranged under 8 general headings. The all-pervading theme of the book is that dogmatic psychoanalysis furnishes the most fundamental explanation of crime, pathological or otherwise. Unconscious motivation is the key. Social problems are distracting, always secondary, and whoever gives them great weight is guilty of over-simplification. Economic motives, in prostitution for example, are especially ruled out and regarded as only "ancillary in nature."

It is Dr. Glover's belief that "possibly all forms of criminal conduct" are the result of a "fundamental flight from reality." The aim of psychoanalytic therapy of the offender is "to resolve the unconscious resistances which obstruct approach to the root causes of his behavior." Even if one assumes that these causes are entirely in the psyche of the individual, one cannot help wondering how such therapy can affect a cure if the offender returns to the same social conditions in which these "root causes" were operative in the first place. Dr. Glover seems to be one of those who believe the only thing that counts is how and when the Oedipus complex is resolved, while everything that happens later is incidental. "A criminal group," he writes, "is one in which the unconscious homosexual impulses (i.e., the negative Oedipus complex) have given rise to friction rather than to cooperation." This represents a one-factor etiology.

Kraepelin used to say, speaking of books like this: "Woher weiss das der Herr Souffl-

so?" (How does Dr. Soandso know that? Where are the clinical cases?) There are practically no case examples in this book, and the number of fully analyzed cases on which all this criminological theory is built is exceedingly small. The book's outlook is unclinical. The author makes no distinction between projective tests and the questionnaire method, though whereas the latter is unscientific and often misleading, projective tests have found a definite place in clinical work. The Gluecks' prediction tables are based not on "tests" but on the questionnaire method. The Rorschach test, on the other hand, was devised by a brilliant psychoanalyst and would have been impossible without psychoanalytic principles.

Speaking of the M'Naghten rules, Dr. Glover advocates that definite mental diseases should be specified by law. Quite apart from the fact that the law can classify only crimes, and not diseases, the list he gives is pre-Kraepelinian and unclinical. Manic-depressive psychosis is not just a "disease of the emotions," nor are paranoia and schizophrenia "diseases of the reality and social sense" nor compulsive states a "disease of the reasoning capacity." And if we are to speak of "diseases of the moral faculty," who is to be the judge of what they are, and by what criteria?

When "team research" in crime is discussed, it is especially pointed out that sociological data are never causal, but are merely "precipitating factors." And it is significant that in the enumeration of all those to be included in such a team, psychoanalysts, psychologists, statisticians, *et al.*, lawyers are completely omitted. The author is critical of the legal profession, speaks of judges who sit with "terrified obstinacy" and says: "The ultimate issue is not whether psychiatrists can write reports, but whether magistrates can be trained to read them." Having read very many reports and known many judges, I feel the opposite is true. It is not a question of whether judges can read, but of whether psychiatrists will write reports that are factual, scientific and understandable. The author's attitude about lawyers is in line with a lack of awareness of the history of the law, of law formation generally and of the concrete social conditions under which the majority of the population has to live. What is lacking in the author's socio-legal discussions is recognition of the necessity of safeguarding not only the health of an individual, but his rights as well.

This review does not do full justice to this big, well-written book which contains so many stimulating discussions that it can be read

with advantage by anybody interested in crime. The general views it expresses are the ones predominant in the literature of American forensic psychiatry today. That is why it seems necessary to point out that there is another side to this individualistic, subjective perspective. While the psychiatrists claim that the lawyers are backward, the lawyers feel that many psychiatrists are forward. If psychiatrists want to deal with crime realistically, they must assess the limitations of their own methods more self-critically, and realize the tentativeness of their speculations.

Dogmatic psychoanalysis as applied to social problems is a tragedy: yesterday's advocate of the new has become a prop to the old; yesterday's revolutionary has become today's reactionary. Psychoanalytic psychiatrists have attained the status of a privileged class. We have learned to trace the unconscious disguises and ramifications of the instincts. But have we learned to recognize the equally unconscious bias of our own social position when we are dealing with the multitudes of underprivileged people who fall into crime after stumbling over obstacles more massive than the "negative Oedipus complex?"

FREDERIC WERTHAM, M.D.,
New York City.

THE TESTING OF NEGRO INTELLIGENCE. By
Audrey M. Shuey. (J. P. Bell Company,
pp. 341.)

Doctor Shuey, Chairman of the Department of Psychology of Randolph-Macon Woman's College, has reviewed, in this volume, the differences between whites and Negroes observed in the results of intelligence tests.

Doctor Shuey concludes that the regularity and the concordance of results attest to an hereditary basis for those observed differences. Doctor Garrett, Professor Emeritus of Psychology at Columbia University maintains that the proofs adduced justify that conclusion.

This volume assumes particular importance when we bear in mind the uncertainties and discrepancies which bedevil specialists of this material.

It is useful to recall, at this point, that Unesco assigned the task of formulating a "Statement on Race" to a commission of specialists. In their conclusions they maintained: "Available scientific knowledge provides no basis for believing that the groups of mankind differ in their innate capacity for intellectual and emotional development"; and "When . . . two groups have been brought up from childhood in similar environments, the differences are usually very slight . . ."

Serious protests, with respect to these conclusions, were raised by specialists to whom they were submitted.

One could contend that since not a single experiment, in which two groups of individuals selected from two diverse races, having been raised since childhood in similar environmental circumstances and subsequently subjected to intelligence tests, had been conducted, the declarations above reported can be considered without foundation.

It is not likely, furthermore, that human groups, which display innate differences for all the physical and psychical characteristics which have been studied should reveal themselves substantially equal with respect to intellectual and emotional capabilities.

Does the volume of Professor Shuey furnish the basis, until now lacking, to establish the existence of innate racial differences in the sphere of intellectual ability?

In my opinion it is probable that the volume will arouse objections and discussions because the techniques and the employment of intelligence tests involve, for the time being, very subjective elements, but because of the abundance of the material collected and objectively reported, the volume constitutes a milestone in this area. After its publication the burden of proof rests upon those who reject its conclusions.

In fact the conclusions herein considered accord themselves well with certain theoretical considerations.

I contend, in fact, that one can formulate the following theorem: *If, in a stable environment, two groups of individuals differentiate themselves by virtue of a character which, at least in part, is hereditary and which, at least in one of the two groups, is subject to natural selection, the differences observed between the two groups are, at least in part, innate.*

If for the two groups the environment (taken in the broadest sense of physical and social environment) is identical, the differences of character between the two cannot depend upon the environment and therefore must be innate.

If the two groups live, instead, in diverse environments, and in both or at least one of these, the characteristic considered is subject to natural selection, this will eliminate certain particularities of character and favor others—and in a different manner in the two groups—and if these differences are in part hereditary, there will result, in successive generations, between the two groups, to a certain degree, innate differences.

This is with the qualification that the environment remains stable in such a fashion that

heredity and natural selection have had the time to exercise their influence.

Now, intelligence is certainly, in man, a characteristic in part hereditary, and certainly it is subject to natural selection, in such a manner that the intellectual and emotional differences which are encountered with respect to various populations must be in part innate.

Therefore it can be said that, under the influence of natural selection, innate mental capacities differ among various population groups.

To admit, among the various human groups, innate differences is not the same as admitting that some group is—by virtue of innate quality—superior, and some other inferior.

One cannot, however, exclude the possibility that one group finds itself inferior to another with respect to all the mental traits if it lives in an environment in which mental characteristics assume a minor, and physical characteristics assume a major, importance—in such a manner that natural selection would have favored the development of the latter to the disadvantage of the former. This may have been very well the case with respect to Negro populations.

But it can happen (and this seems to be most frequently the case) that selection exercises itself upon mental characteristics not only intensively but selectively, in such a fashion that each group possesses the innate mental and emotional dispositions best adapted to the environment in which it lives.

From this it follows that while the primitives find themselves in a condition of inferiority in civilized society they are superior to non-primitives in their own environment. The evaluation of superiority and of inferiority, of one or the other group, is thus far subjective.

Before concluding I should like to insist upon two points.

The first is that the development of intelligence is important for the success of an individual and a collectivity, but there are other qualities—among which are the disposition to labor, pertinacity, honesty, conformity or vice versa, the inclination to independent thought, social solidarity, more or less easy contentability, optimistic or pessimistic temperament—which can have much more importance for the technical, economic and cultural progress of society.

The disposition to labor, in particular,¹ has

¹ Cf. C. Gini, "Caratteristiche e cause della primitività," *Genus*, V, #3-4, 1942, *Las Poblaciones Primitivas*, Cuadernos de Extension Universitaria, Buenos Aires, 1955, *Economía Laboral*, Editorial Labor, Barcelona, 1954.

been, more than intelligence, the decisive factor in the progress of society from the animal level of production to the level, toward which it tends, of spontaneous labor.

So much more is it necessary to keep in mind the other factors when we realize that intelligence does not always accord itself with other favorable attributes; thus, there is a negative correlation between intelligence (the desire to know) and the disposition to conform.

The second point is that if in the individual, intellectual capacity contributes to his success the higher its level, it does not follow that a society finds itself in a position correspondingly advantageous the higher the intellectual average of its members. That depends on the type of social organization. For each type of organization there is an optimum in the distribution of the various aptitudes.

A small group of persons of high intellectual capacity, directing a mass of persons of lesser ability but given to work and conformity, could conceivably enjoy an advantage over a nation in which each member is gifted with superior intelligence and who, as a consequence, is little disposed to follow the orders of others without criticism or resistance.

This is one circumstance which must be kept well in mind in the judgment of the qualifications of nations in international competition.

President, International Institute of Sociology.

HEREDITY AND HUMAN NATURE. By David C. Rife. (New York: Vantage Press, 1960, pp. 265. \$4.50.)

This is an excellent elementary introduction to the study of the genetic bases of man as a behaving organism. A refreshing forthrightness is among the many qualities which should recommend this book to those readers who are unafraid to look a fact in the face, however challenging of well-intentioned orthodoxies it may be. Dr. Rife believes that human beings are unequal, and that there is nothing to be gained by asserting the contrary in the face of the facts. On the other hand, he believes that by acknowledging the facts it will be possible to deal with them more effectively. His book is an admirable exposition of the biological basis of inequality, while it insists at the same time on the right of every human being to equality of opportunity to develop his potentialities.

Dr. Rife's brief exposition of the mechanisms of heredity are admirably clear, and it is a pity his publisher has not served the author better in the reproduction of the tabular matter and figures. The author misunderstands some of the

assertions made in the *Statement on Race* issued by UNESCO. For example, on the UNESCO assertion that "Most anthropologists do not include mental characteristics in their classification" he comments, "This is baffling and seems to be beside the point." Anthropologists cannot use mental characteristics for the purposes of classification for the simple reason that such characteristics are to a very considerable extent determined by cultural factors, and the taxonomic procedures of the anthropologist are based on morphology and not on the shifting sands of culturally conditioned traits.

Dr. Rife believes that the evidence supports the view that "races" differ in mental characteristics. This is a matter which will long be under debate, but to which future research will alone be able to return the answer. Dr. Rife may turn out to be right, but I do not think that, on the basis of the evidence at present available, it is possible to say anything other than that if such differences will eventually be found to exist, the general, nay, the universal rule will always remain applicable, namely, that by virtue of the fact that all men are human they are entitled to the fullest rights to the development of their potentialities, whatever they may be. This is a view to which Dr. Rife makes it unequivocally clear he fully subscribes.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

FUNDAMENTALS OF CHILD PSYCHIATRY. By Stuart M. Finch. (New York: W. W. Norton & Company, 1960, pp. 324. \$5.95.)

This reviewer's appetite was, immediately upon opening the book, whetted by a glance at the Table of Contents; the sequence of the 15 chapters indicated from the start a capacity for clear organization of the vast and multifaceted issues which have their rightful place under the heading of child psychiatry. In a brief preface, the author states his aim as one of presenting the material to "the new student in medicine, psychology, social work, pediatrics, and nursing" as "a broad base for subsequent more specialized courses." This purpose has been achieved with remarkable skill. The style is lucid and devoid of any excursion into would-be professional gobbledygook. The case illustrations are well-chosen and enhance the student's orientation derived from the more general treatment of the problem which they illustrate. It is easy to agree with the publisher, who points on the jacket to the excellence of the specific examples.

There is a refreshingly pluralistic outlook which advises the consideration of "all the

factors" (genetic, physical, emotional) which "will have varying degrees of importance in each case." There is an especially good chapter on parental psychopathology with well-outlined sketches of family types and parental personalities and a summary in which there is much wisdom. A chapter on "special considerations" offers valuable hints to the students on items such as illegitimacy, adoption, foster home placement, divorce, orphanages, hospitalization, and religious differences.

So far so good—much better than good. But one wonders what the beginner (for whom the book is intended and does such a splendid job) is to make of the first chapter. In it, psychoanalytic theory is outlined as the "basis" of child psychiatry on a few pages offered *ex cathedra*. Phases of psychosexual development and mechanisms of defense are presented as a sort of glossary of analytic terms. The definitions as such are apt and succinct but what is the student to do with them after he has committed them to memory? As he goes on with the rest of the book, the occasional and definitely not obtrusive references to orality, anality, and oedipal period must appear to him as foreign bodies in an otherwise beautifully clear and consistent content. One cannot get rid of the feeling that the author has had the need to acknowledge his allegiance to analytic doctrine and that the book might be more enlightening to the novice if he were spared the task of trying to integrate a few memorized bits of sectarian theory with the highly practical and informative discussions in the subsequent chapters. Is it really helpful to the student to start out with the reading of an unsolicited loyalty oath on the part of an author who, having declared his allegiance, proceeds to give so excellent an account of the fundamentals of child psychiatry?

Except for the puzzle created in the student by the first chapter and some sporadic references to it in the text, this is a magnificently written, "basic yet comprehensive book" (statement on the jacket) which bespeaks the author's great competence as a clinician and teacher.

PROGRESS IN PSYCHOTHERAPY, VOL. 5. Edited by Jules H. Masserman, M.D., and J. L. Moreno, M.D. (New York: Grune and Stratton, 1960, pp. 262. \$8.50.)

Under the subtitle, "Review and Integration," this 5th volume in the series presents some 32 papers by specialists in psychotherapy. Beginning with an introduction by editor J. L. Moreno, the papers are presented under

the headings "History and Review," "Fundamentals of Psychotherapy," "Methods of Psychotherapy," "Special Techniques," "Current Applications," "Interdisciplinary Integrations" and "Developments Abroad," with a concluding paper by editor Jules H. Masserman.

P.P.T.

EPIDEMIOLOGY AND MENTAL ILLNESS. By Richard J. Plunkett, M.D., and John E. Gordon, M.D. (New York: Basic Books, Inc., 1960, pp. 126. \$2.75.)

This is one of a series of reports made for the Joint Commission on Mental Illness and Health as a basis for possible federal and state mental health programmes. Here the authors plainly set forth the serious limitations in current scientific knowledge which make it difficult to establish the nature, cause and control of mental disorder—its relationships to the manifold conditions of life—heredity and environment. They point out clearly the shortcomings of past community surveys which failed to advance materially our knowledge. And, although they make pertinent suggestions for further studies, they recognise that they are offering "no easy detours" to gain a basic understanding of one of the most important public health problems.

This fascinating and informative little volume, pleading for full facts to replace half facts, fads, fancies and fallacies, should be read by all in the psychiatric and general medical fields. Congratulations on its content and form are quite in order.

NIEL E. MCKENNON, M.D.,
University of Toronto.

AFRICAN HOMICIDE AND SUICIDE. Edited by Paul Bohannan. (Princeton, N. J.: Princeton University Press, 1960, pp. 270. \$6.00.)

This excellent volume constitutes a striking example of the value of the comparative anthropological method in producing insight and understanding of complex forms of behavior. Dr. Bohannan has stimulated the production of systematic studies of homicide and suicide in 7 African tribes, 2 by himself and 5 by other anthropologists. The subject is introduced by the editor with a consideration of theories of homicide and suicide, and is concluded by him with an illuminating analysis of the studies reported in this volume on patterns of murder and suicide.

The anthropologist would expect to find cultural factors playing the dominant role in determining patterns of homicide and suicide, and that, indeed, is what Dr. Bohannan finds.

But if the universal likenesses are impressive, so are the differences, if only, again, because they underscore the importance of cultural factors in conditioning human behavior.

This volume constitutes a major contribution to the subjects of which it treats. All students of human behavior will benefit from its study.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

THE METABOLIC BASIS OF INHERITED DISEASE.

Edited by John B. Stanbury, James B. Wyngaarden, and Donald S. Frederickson.
(New York: McGraw-Hill Book Co., 1960,
pp. 1,447. \$30.00.)

In 1908 Sir Archibald Garrod took for his Croonian Lectures the Subject of *Inborn Errors of Metabolism*, published as a volume in 1909 and again in 1923. From his observations on certain lifelong diseases Garrod concluded that they probably originated as a result of the reduced activity or absence of a single enzyme governing a single metabolic step. Fifty years later Garrod's brilliant inference was triumphantly proven when La Du, *et al.*, demonstrated, in 1958, the absence of homogenistic acid oxidase activity in the liver of a patient with alcaptonuria.

The present admirable volume provides a complete survey of all inborn errors of metabolism thus far uncovered. The editors have called upon a whole regiment of experts each of whom writes on the inherited metabolic disorder with which he is most familiar. The clinical, biochemical, and genetic information is most readably and graphically set out, so that the uninitiated reader may gain from this volume almost as much as the expert will. There is an introductory chapter on elementary principles, and there is a final chapter on how to keep records of such conditions.

Most commendably the editors have attempted to emphasize the necessity of uniformity in a terminology which traditionally bristles with the most sesquipedalian of synonyms. It is to be hoped that, short of an International Committee, that Stanbury, Wyngaarden, and Frederickson will become the ultimate arbiter on terminology.

The book has been admirably produced, and is especially appealing to all students of human behavior. If there is one criticism it is that some of the contributors rather loosely used the term "race," and altogether misuse that unpardonable term, "Nordic." The bibliographies are exhaustive, and there is a thorough index. The editors and contributors and the publishers are

to be congratulated upon the publication of this eminently useful book.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

THE ARCHETYPES AND THE COLLECTIVE UNCONSCIOUS. Coll. Works Vol. 9: Part 1. By C. G. Jung. Translated by R. F. C. Hull. (Bolligen Series XX. New York: Pantheon Books, Inc., 1959, pp. 451. \$7.50.)

This book is the first of two volumes presenting Jung's concepts of the archetypes and the collective unconscious. It consists of essays written from 1933, although the beginnings of these themes may be noted in his papers as early as 1902.

Prof. Jung is well known as a profound student and accurate observer and his contributions, which include an extension of the knowledge of schizophrenia, the elaboration of association tests, the differentiation of personality types, the advancement of the knowledge of symbolism, and the enrichment of the whole field of racial psychology, are of far reaching intellectual, psychological, and psychopathological significance. Jung has often been misunderstood and misinterpreted in some of his theories. His early writings were somewhat involved, particularly for the beginner, as his books on the psychology of dementia praecox, and a later one on the psychology of the unconscious are rather heavy going for those not well grounded in ancient and racial lore.

The theoretical basis for the particular concepts presented in the present book is given in the first 3 essays. These are followed by 8 essays covering the topics describing mother and child archetypes, the psychology of the spirit in fairy tales, studies on individuation and those concerning mandala symbolism, as well as other related subjects.

In the section on the "Psychological Aspects of the Mother Archetype" Jung explains clearly what he understands of the nature of the archetype. "Again and again I encounter the mistaken notion that an archetype is determined in regard to its content, in other words that it is a kind of unconscious idea (if such an expression be admissible). It is necessary to point out once more that archetypes are not determined as regards their content, but only to a very limited degree. A primordial image is determined as to its content only when it has become conscious and therefore filled out with the material of conscious experience . . . the representations themselves are not inherited only the forms, and in that respect they correspond in every way to the instincts, which

are also determined in form only. The existence of instincts can no more be proved than the existence of the archetypes so long as they do not manifest themselves concretely."

The last two essays are illustrated by 79 half tone plates, of which 29 are in color. The mandala symbolism is described in detail and beautifully illustrated. There are 27 pages of classified bibliography and the text is adequately indexed. A review of the productions of this famous scholar makes extremely interesting and informative reading.

NOLAN D. C. LEWIS, M.D.,
Princeton, N. J.

TREATISE ON NERVOUS DISEASES. 3rd ed.

- By Mario Gozzano. (Milano: Casa Editrice Dr. Francesco Vallardi, 1959, pp. 929.)

The clinical discussions and differential diagnosis in this well-printed textbook on neurological diseases are excellent, full of sober judgment and often qualified by cautionary asides to prevent the inexperienced reader from falling into excessively rigid or literal interpretations. The considerable clinical experience of the author is evident and permeates the whole text. The book is readable, very didactic and full of thoughtful discussions.

The most glaring fault in the book is the absence of bibliography. Books of this kind are used by students, practitioners and interested specialists as take-off points and as guides to the relevant literature on the subject. Russell Brain's neurological textbook is, perhaps, the best example of the value of a few well chosen key references placed at the end of each chapter and in Dr. Gozzano's book this would be a most welcomed feature.

If the text is up to date in certain details (*i.e.*, treatment) in others it has a "dated" look and the theoretical thought seems to stop short with Sherrington. The work of Moruzzi, Magoun, Jasper, *etc.* passes unnoticed except for an occasional nod here and there. Three pages are devoted to Apathy's and Bethe's old work on neurofibrils, transmission of nerve impulse and the theory of the neuron but no mention is made of the modern work with the electron microscope. Chronaxies are still used to explain basic facts of neurophysiology but the fundamental work of Hodgkin, Huxley, Katz and others on nerve impulse transmission passes unnoticed.

This reviewer would also express some reservations about the purely anatomical order of exposition (diseases of the hemispheres,

of the cerebellum, of the brainstem, of the spinal cord, *etc.*). Granted there is no such thing as a perfect classification of neurological diseases and that an anatomical order is simple and follows the classic tradition, nevertheless it is also true that this is hardly suited to today's approach which is more physiopathologic, etiologic and closer to internal medicine. For instance, the large group of spinal cerebellar degenerations are dealt with in piecemeal fashion under the chapters "cerebellum," "spinal cord," *etc.*, thereby losing the unity of concept linking these heredo-degenerative diseases with other hereditary conditions affecting muscle, peripheral nerve, posterior roots, and/or spinal cord. Acute disseminated encephalomyelitis together with Devic's disease, multiple sclerosis and Friedrich's disease, are considered to be affections of the spinal cord, which they are not, while the more comprehensive concept of "leukoencephalopathy" or "demyelinating disease" is nearly lost. It would be perhaps commendable to suppress references to exceedingly rare conditions (like Mills' Syndrome for instance) and to enlarge instead the chapter on muscle diseases adding some of the "new" processes like polymyositis, thyrotoxic myopathy, myopathy in visceral cancer, menopausal myositis, *etc.* Progressive nuclear ophthalmoplegia should be included as a myopathy (Kiloh and Nevin) rather than persist in considering it neural in nature. Other details are merely oversights. For instance, on page 352 it is said that headache from brain tumors is worse on standing and improves on lying down, while the consensus, at least on this side of the ocean, seems to be the other way around. The old work of Schiff-Wertheimer shows the posterior limb of the internal capsule to be supplied by the anterior choroidal artery but it is wrong to assume (p. 101) that occlusion of this vessel leads to softening of the area and to complete hemiplegia; repeated surgical ligation of this vessel for the treatment of parkinsonism (Cooper) have failed to substantiate this view.

The author himself says in the introduction "scientific research is in continuous evolution and the new acquisitions rectify previous interpretations." There is no doubt that such an excellent, didactic and complete textbook will achieve many editions in which the old dictum "nuova construege sed amplia vetusta servare" will be fully realized. It deserves it.

J. M. SEGORRA, M.D.,
Boston, Mass.

TRAITE DE PSYCHIATRIE. By H. Baruk. (Paris : Masson & Cie., 1959, pp. 1569, 2 volumes.)

This *Treatise of Psychiatry* by the internationally renowned French psychiatrist approaches in size the dimensions of a Handbook of Psychiatry, written by one author. To the more widely read, Baruk needs no introduction. He is professor of mental diseases at the University of Paris and physician-in-chief of the famous Maison Nationale of Charenton, a government mental institution, which corresponds in this country to St. Elizabeths Hospital in Washington, D. C.

The first volume opens with a chapter on the personality and discusses what psychiatry, psychology with its multitude of tests, and even philosophy can contribute to this problem. The influence of dynamic personalities on others is exerted through suggestion and domination, while all too often the better judgment and healthy critique of others is annihilated by their dynamism. In a hypomanic phase such an individual may become cynical and act without scruples. Under more abnormal conditions there may then occur varied grades of personality disorganization, associated with aggressive acts or ideas of persecution. The author then takes up the methods of examining the mental patient, which should include a neurological as well as a complete physical examination made by the psychiatrist. In the section of psychopathology, there is a clear account of anxiety, depersonalization, melancholia, mania and hypomania, mental confusion, hallucinations, the Kraepelinian "dementia" in schizophrenia, and the organic dementias.

The second volume is given over to therapeutics and etiology, and deals with the various kinds of shocktherapy, chemotherapy, psychosurgery, and the tranquilizers. There is a discussion of the dynamic causes, which may give rise to psychopathologic syndromes, reserving here also a place for moral factors.

Under the heading of toxic-infectious etiologies there are described the psychoses caused by infections, such as general paralysis and other encephalitides (von Economo). There is an adequate chapter on rheumatic fever, which is reintroduced into psychiatry, and which is

becoming recognized everywhere, even in Iron Curtain countries, as the most important and frequent cause of the chronic infectious psychoses. They represent the many patients with rheumatic heart disease (usually mitral stenosis) in mental institutions, in whom the smouldering rheumatic infection on the heart valves has also involved the brain in the form of a recurrent rheumatic obliterating endarteritis, mainly of the small meningeal and cortical vessels, producing gross and microscopic infarctions in the cortex. The entire clinico-anatomic complex is referred to as rheumatic brain disease, late sequel of rheumatic fever. It is more frequent among women, the ratio between women and men being 3:1. The condition can be successfully treated with a combination of penicillin and steroids (cortisone).

There are chapters on psychosomatic medicine, and on mental symptoms provoked by such diseases as hepatitis, dysentery, hypertension, etc. Furthermore, mental disturbances with an underlying endocrine background (Bleuler), and those brought on by brain trauma and cerebral tumors, are thoroughly discussed. The theme of cerebral arteriosclerosis and of the senile psychoses is somewhat brief, considering the increasing importance of this group of mental patients.

The manual is concluded with a large section, which Baruk calls psychiatric humanism, and which includes what is known to the American psychiatrist as the sociological and cultural aspect of mental disease. A chapter on war psychiatry is added here. There is a stimulating discourse on the psychotherapies and Freudian psychoanalysis, which makes particularly illuminating reading because Baruk is also a scholar of the Hebrew language, literature, and history.

This handbook offers an excellent source of information on contemporary French psychiatric thinking and practice—and for that matter, of continental European psychiatry. In this country, the use of the book, being written in a foreign language, will unfortunately be limited, but it should be available in the libraries of all American medical schools.

WALTER L. BRUETSCH, M.D.,
Indianapolis, Ind.

EVOLUTION OF MENTAL HEALTH PROGRAMME IN TAIWAN

TSUNG-YI LIN, M.D.¹

A brief description of the conditions in 1946 when modern psychiatry was introduced in Taiwan may be necessary. The handing over of the Japanese Administration to the Chinese resulted in the complete overhaul and reorganization of political, military, social, economic and educational systems as well as in a change of official language. The Government was burdened by many important cares. The public, with little preparation, was absorbed in the effort of adjusting to a difficult transitional situation. The medical and public health professions were busy in their immediate tasks of combating the acute infectious diseases and restoring the services to the pre-war level which the inhabitants used to enjoy.

The situation regarding psychiatry can be easily summarized in one word: a vacuum. Since the Japanese psychiatrists had been repatriated and there was not one native Chinese sufficiently trained in this field, the only Government Mental Hospital with a capacity of 100 beds and two other public institutions run by charity organizations with 50 and 70 beds each merely housed un-cared-for lunatics. The Department of Psychiatry of the University Hospital was a deserted building filled only with cases of glass-ware and books, most of them useless. The general attitude of the medical profession as well as the lay public to psychiatry was characterized by indifference and contempt arising from their ignorance and also prejudice against mental illness. One more factor contributed to this negative attitude to psychiatry: there was a general belief that Chinese society needed little psychiatry because of its traditional philosophy and extended family system which act as protections against mental illness.

The task of initiating a psychiatric and mental health programme in Taiwan under such almost impossible circumstances presented an exceptional challenge to the

writer. After reviewing the situation and after considerable deliberation, it was clearly realized that no blue-print or precedent was available to act as a basis for the mental health planning in Taiwan. For such a situation, where a society with traditional Chinese culture and social institutions was experiencing transitional uneasiness arising, not only out of the political situation but also from rapid industrialization and modernization, was unique and therefore called for special consideration and careful planning. The plan had to be realistic, sensible and dynamic.

The first step was to define the magnitude of the problem by determining the prevalence of mental disorder in the community.

THE SURVEY AS A BASIS FOR MENTAL HEALTH PLANNING

Census surveys of a sample population in three communities—rural, small town and urban—were carried out from 1946 to 1948; altogether 19,931 people in these communities were studied. The aims of these surveys were:

1. To assess the mental health needs of the community through objective data on the prevalence of mental disorder.
2. To understand the available resources in the community through the study of the actual care of the mentally ill and the attitude of the family and society in general towards them.
3. To provide reliable data to be compared with those from other cultures.
4. To collect objective data on mental disorder and socio-cultural (ecological) factors in this community to gain an understanding of their relationship.

The research method and the results obtained are reported elsewhere(3). In this connexion only those findings which helped to formulate basic principles for a mental health programme and to establish priorities will be discussed.

The finding that 10.8 per 1000 in the

¹ Professor of Psychiatry, National Taiwan University, Taipei, Formosa.

sample population suffered from mental disorder needing psychiatric attention challenged the prevailing misconception that Chinese society was free from mental illness, and showed the problem to be of the same magnitude as in other societies. The fact that the great majority (over 95%) of the psychiatric cases were untreated provided further convincing evidence of the needs for a mental health programme. Upon the presentation of the data of the survey, the medical profession and health authority were stimulated to revise their traditional views of psychiatry and to pay more attention to the psychiatric problems of the community. In other words, the survey helped to create a more favourable attitude to a mental health programme on the part of medical and health authorities.

The pre-survey impression that Chinese society has a high threshold of tolerance to deviant behaviour was confirmed by the survey. This observation led to a basic and important query about the wisdom of developing a mental health programme along the traditional pattern of building mental hospitals. The proper use of the existing resources in the community, such as the strength of extended family relationship as expressed in the responsibility assumed by the family for the welfare of each member, became the central interest of the mental health planning.

Given the lack of practical psychiatric personnel of any category, the magnitude of mental health problems revealed by the surveys constituted a special challenge when it came to formulating and implementing a long-term programme. To this end, a 25-year mental health programme was evolved which was divided into three stages to accomplish the three major objectives envisaged:

1. To integrate psychiatry into medicine as a respectable member of the medical profession through the intensification of the teaching of psychiatry in the medical school.

2. To integrate mental health into public health practice.

3. To instill sound mental health principles into the general educational scheme.

SETTING UP A PSYCHIATRIC CENTRE AT THE UNIVERSITY HOSPITAL AND DEVELOPMENT OF A NUCLEUS OF STAFF AND INSTRUCTORS

It was argued that, unless psychiatry were accepted as a legitimate scientific discipline and a respectable member of the medical profession, it could have no prospect of future development; the logical place to foster its acceptance is through the medical school. The resistance to psychiatry on the part of both faculty and students was clearly apprehended. The social stigma attached to psychiatric illness, prejudice against the scientific grounding of the psychological sciences and disrespect for the psychiatrist as a fully-fledged member of the scientific and medical professions were widespread. The first and essential task had to be "educational" and two closely related projects were initiated: the establishment of the Department of Neurology and Psychiatry of the University Hospital and the intensification of the teaching of psychiatry to undergraduate medical and nursing students.

The functions envisaged for the Department of Neurology and Psychiatry are the following:

1. The location of the Department of Psychiatry in the University Hospital should provide a physical demonstration that psychiatry is part of medicine and should also facilitate a close collaboration between psychiatry and the other medical disciplines.

2. An active university department should serve as a centre of psychiatric treatment to show both the medical profession and the general public, who were firmly wedded to the idea that mental disorder was incurable and hereditary, that psychiatric illness can be treated and cured.

3. This should make psychiatric service of a non-custodial nature accessible to the patients and general public, and help to do away with the old associations of "mental illness—lunatics—asylums—bars and walls."

4. The Department should develop into a community mental health centre, equipped with such facilities as a social and domiciliary service, a children's clinic, a day hospital, etc.

5. The last and most essential function is to serve as a centre for teaching, training and research without which no sensible programme can be evolved and implemented.

The immediate task in the establishment of the Department was to secure and train a nucleus of staff capable of carrying out the clinical functions and also to develop a group of instructors for teaching and research. Fortunately, from the start, two to three intelligent medical graduates joined the Department each year for training in psychiatry. The training was done through supervised clinical work and group discussions on academic subjects. A few of the trained psychiatrists who showed ability and interest in academic work became instructors and helped with the undergraduate teaching programme which consisted at that time of a total of 64 hours of lectures. They took an active part also in the teaching of the nursing school, and several qualified nurses came every year to the Department for specialization in psychiatric nursing. Thanks to this young enthusiastic staff, the Department was able to establish its routine clinical service and also carry out the survey work.

Advanced training for the teaching staff started in 1950 when the writer, through the American Bureau of Medical Aid to China and a Harvard Research Fellowship, spent two years at the Boston Psychopathic Hospital. A Chinese psychiatric social worker, trained at Simmons College, who had had previous experience in Taiwan, joined the Department in 1953. Two more psychiatric instructors who had spent 5 to 7 years in the Department received advanced training in the United States and Canada.

The World Health Organization started its aid to the mental health project in Taiwan in 1955 and has generously and most effectively assisted in the advanced training of the teaching personnel in psychiatry and mental health. Two psychiatrists received one-year fellowships, one in the United States and the other in Europe; one clinical psychologist and one child psychiatrist studied in the United States for two years; one nurse in the United States for two years and two nurses two years each in the United Kingdom and the United States.

The formation of a nucleus of qualified staff at different disciplines and the prospect of more of them in the near future have made it possible to plan and implement a long-range programme. The basic principle

adopted was that no programme should be planned without preparation of the personnel and every project, clinical or otherwise, should include training as an essential aspect of its design.

INTENSIFICATION OF THE UNDERGRADUATE TEACHING OF PSYCHIATRY

Nevertheless, under the circumstances in 1946 in Taiwan, the choice between the intensification of undergraduate teaching of psychiatry to medical students and the training of specialized personnel such as psychiatrists, psychiatric nurses, psychiatric social workers and psychologists was not hard to make. The experience of the "advanced" countries had already clearly indicated that the training of specialized personnel alone never catches up with the needs of the community. Emphasis was to be laid, it was decided, upon the integration of psychiatry into the medical and nursing curriculum to teach students to understand and forward the mental health programme. Properly trained general physicians should be able to handle mild psychiatric problems. Home care and rehabilitation programmes should be the main line of development in the mental health programme and therefore local practitioners should be trained in this respect. Moreover, the attraction of young intelligent and properly motivated graduates to psychiatry as a specialty was essential.

The character of the medical curriculum is difficult to change, particularly when it has to do with psychiatry. A combination of circumstances made it possible to remodel the teaching of psychiatry at the National Taiwan University Medical College according to the policy formulated above. In 1953 and 1954 the medical curriculum of the University underwent dramatic revision: to increase efficiency the "block system" of teaching was adopted and teaching hours redistributed in accordance with modern medical trends. The recommendations regarding psychiatry of the two advisers on medical education² came as a surprise, both to the non-psychiatric faculty and to the

² Dr. H. Brown, Dean of the School of Public Health, Columbia University, and Dr. W. G. Davison, Dean of Duke University Medical School, were ICA medical education consultants in Taiwan in 1953 and 1954.

psychiatric department, because in the place of 64 hours of lectures on psychiatry for the whole medical curriculum, 16 hours were to be given as a course in medical psychology and 14 hours for neuropsychiatric diagnostics in pre-clinical years; each student was to have clerkship training for 9 full weeks, half of the students were to spend an additional 6 or 7 weeks as interns in the final year. This intensification of psychiatric teaching naturally was regarded by the other departments as an invasion and certainly presented a formidable task to the understaffed Department of Neurology and Psychiatry. The timely publication of the report of the Ithaca Conference (1952) made this seemingly impossible teaching load appear as both a challenge to take its share of responsibility in medical education and an opportunity to forward the advance of psychiatry.

The teaching programme is described elsewhere(4, 6) and only an outline is briefly given here. The lectures on medical psychology cover the principles of human behaviour and the growth and development of personality, particularly in relation to Chinese society and culture. The course on psychiatric diagnostics prepares the student for a better understanding of the psychology of the ill, the recognition of the subtle and gross signs of emotional and behavioural disturbances, interviewing technique and the doctor-patient relationship in a medical setting. The 9-week psychiatric clerkship training programme is characterized by the students' active participation in clinical work mainly with ambulatory patients and by academic instruction in seminars. The daily clinical work with one ambulatory patient helps the student not only to see the most common types of patients, but also illustrates for him the kind of problems which call for psychiatric attention. This experience is augmented by the daily case conferences of the Department which acquaint the student with the multidisciplinary intensive approach of the psychiatric team. The 60 subjects included in the seminars not only deal with clinical psychiatry and psychotherapy, but also cover such areas as the biological basis of mind, personality development and child psychiatry, psychiatry and medicine (psychosomatic

medicine), the mental hospital, mental health (psychiatry, community and law). Through these seminars the student obtains a general picture of the current problems and trends of psychiatry and also the position and role of psychiatry in relation to medicine, public health and society.

Neurology is taught with psychiatry as an integral part of the curriculum and is presented so as to help the student understand the integrative function of the central nervous system in relation to outside stresses and also to the internal organs.

Another feature of this teaching programme is the strong emphasis on the students' active participation in the learning situation and the encouragement of self-education and critical thinking. Students are also encouraged to participate in ongoing research projects to which many of them respond with enthusiasm. An average of one-fifth of the students choose a subject in psychiatry for graduation thesis. These research activities have been regarded as a most fruitful experience both by the students and the staff.

One half of the students take up psychiatry as part of their rotating internship training for 7 weeks before graduation. The limit on the number of students is due to the limited facilities available. The aims of the intern training are to develop the students' understanding and skill in psychological medicine, in order that they may deal with mild psychiatric problems with greater confidence. For this, three types of instruction are given. First, psychotherapy of two patients under supervision, secondly, actual experiences in dealing with psychiatric problems in the emergency clinic, and thirdly, further experience in a ward with treatment procedure, physical as well as occupational and rehabilitational.

The results of the teaching programme still remain to be seen and a careful evaluation is indicated. The encouraging response to it may, however, justify the view that this programme should continue. The morale of the staff has risen substantially since the inception of the programme; this is equalled by the students' genuine interest in psychological medicine, which has replaced their original anxiety and prejudice. The appreciation shown by the students

for the teaching method which is strongly biased towards self-education is most encouraging. The increase of more intelligent consultations on psychiatric problems from other departments may also be the result of the extensive psychiatric instruction. This teaching programme, however, may and will change in accordance with the scientific evolution and the needs and resources of the time. The clear recognition of its dual responsibility in taking a proper share in medical education and in preparing the ground for the growth of psychiatry and the mental health programme should guide the future development of the programme.

POST-GRADUATE PSYCHIATRIC TRAINING PROGRAMME AND THE TRAINING OF OTHER PERSONNEL

With the growth, both in number and quality, of the staff and the increasing applications for specialist training, the time was felt to be ripe for the organization of a systematic post-graduate training programme in 1956. The extensive trip made by the writer, sponsored by WHO, to the United Kingdom, Europe and a number of Asian countries made a timely contribution to the shaping of this programme. Many useful observations were made and ideas obtained, both from visits to highly developed psychiatric centres and from contacts with colleagues engaged in pioneer work in mental health in the developing countries.

A few principles were formulated for the post-graduate training programme of psychiatric and mental health personnel :

1. The post-graduate training should be obtained locally, in order to familiarize the trainee with the common clinical problems and the needs and socio-cultural backgrounds of the patients, as well as with the philosophy and the state of development of the mental health programme in Taiwan.

2. No one school of thought should be adopted as the basis of theoretical teaching or clinical instruction ; the trainee should be exposed to diverse views of psychiatry and encouraged to develop a balanced scientific viewpoint through critical thinking and reading.

3. Small group discussions, case conferences and seminars should, for prefer-

ence, be the methods employed, and a multidisciplinary team approach should be woven into all aspects of the training.

4. For a few of the staff selected for future leadership, an advanced training abroad should be provided ; in this case, emphasis should lie not on obtaining a degree or diploma, but on widening the scope of the trainee and also on actual experience in specific fields.

The length of the post-graduate course is 4 years ; the first 2 years for training in clinical psychiatry, psychotherapy and clinical neurology, the third year in child psychiatry and psychosomatic medicine, the fourth year in administrative psychiatry, forensic psychiatry and community mental health and experience in teaching. This programme is still at an experimental stage. Though it has been a slow process, a number of trained psychiatrists are now available to meet the expansion of the teaching programme, the community mental health programme and also for the improvement of the Government Mental Hospital.

As regards psychiatric nursing, a more or less similar programme has been adopted, but on a less intensive scale and, it is regretted, with less satisfactory results. This is largely due to the lack of leadership and of sufficiently trained instructors. The situation has greatly improved in the last few years since the arrival of the World Health Organization mental health nursing adviser and is expected to continue to improve with greater speed with the return of fully-trained instructors from abroad.

The other disciplines of the psychiatric team, i.e., clinical psychologist, psychiatric social worker, occupational and rehabilitational therapists, set a more serious problem for both recruitment and training, because these professions have never existed and were unheard of to many people, including some in responsible positions. It was therefore sought, through personal contacts, to get a few young people of unrelated professional background interested in the work and to give them the necessary training. Though work of this type is tedious and frequently very frustrating, the Department now comprises a psychiatric social worker trained in the United States, with three junior workers, a trained clinical psycholo-

gist with a junior staff and two occupational therapists. There is still a long way to go before schools or courses for training these workers, who are so essential to a mental health programme, can be established.

THE PLACE OF NEUROLOGY

Neurology has been an integral and important part of psychiatry, both in the clinical services and undergraduate and post-graduate teaching. Since the psychiatric activities in general are more oriented towards social psychiatry in Taiwan, neurological services have helped to provide a more balanced outlook. As neurology was also a heretofore neglected medical discipline in Taiwan, the difficulties in developing it into a full medical discipline are equal to those encountered with psychiatry. With the gradual growth of the Neurological Division, it is hoped that an independent unit will be established when the fully-trained senior neurologist returns from his training at the National Hospital for Neurological Diseases, Queen's Square, London.

Though not yet fully developed, this Division has made quite remarkable contributions. Several diseases which were believed to be rare or non-existent among the Chinese or the Orientals have been found, such as multiple sclerosis, Spielmeyer's amaurotic idiocy, Sturge-Weber's disease, Wilson's disease. The main clinical and research interests have been in the study of epilepsy, particularly among children. A study of the mental development of 500 epileptics is under way.

The research activities have so far been exclusively in clinical research. Recently a junior psychiatrist, who has finished his psychiatric training, has joined the United States Navy Medical Research Unit No. 2 at Taipei for post-graduate training in biochemistry, with a view to initiating a laboratory research programme in the Department of Neurology and Psychiatry in the near future.

The inclusion of neurology and psychiatry in one department has been a great asset, not only because it has provided the necessary biological viewpoints and skills to psychiatry, but it has also improved acceptance of the whole Department of Neurology and Psychiatry, by other medical disciplines,

since the medical profession looks less askance at neurology than at psychiatry.

MENTAL HOSPITALS AND PSYCHIATRIC SERVICES

It is regretted that the improvement of the Government Mental Hospital and the planning of mental hospital services in general have been, in the first 10 years, out of the central focus of the mental health programme. It proved a practical impossibility radically to improve the conditions at the Mental Hospital without a core of sufficiently trained personnel, let alone to consider building new mental hospitals. The lack of a good psychiatric hospital has in turn, however, limited the scope of the post-graduate training programme, and also the possibilities for large scale training of psychiatric personnel.

It is now planned to build a 400-bed mental hospital in the South of Taiwan and so far wards totalling 120 beds have been completed; this hospital will become an affiliated teaching institution to a new medical college and also to the Department of Neurology and Psychiatry of the National Taiwan University. This programme is largely carried out with ICA aid from the United States of America, both for the construction of the hospital and the training of personnel, undertaken mainly by the Department of Neurology and Psychiatry.

The emphasis in the planning of clinical services in Taiwan will be on setting up psychiatric departments or clinics in general hospitals. The rapidity of this extension of services depends upon the rate at which trained psychiatrists and other personnel become available, and also on the acceptance, on the part of hospital authorities, of psychiatry.

MENTAL HEALTH AND PUBLIC HEALTH

The search for possible and constructive ways of introducing mental health principles into existing public health practice led to the conclusion that the main initial task should be "educational." The preoccupation with control of infectious diseases and reduction of mortality rates on the part of the health authority had, in the past, been too fixed to allow them to turn their attention to mental health. The main interest shown

by them in the subject had been the maintenance of the only mental hospital. Yet the magnitude of the mental health problems revealed by the surveys, the demonstration of the mental health work of the Department of Neurology and Psychiatry, and the increasing interest in psychiatry shown by young medical and nursing graduates combined to influence the attitude of the health authorities and the medical school, and resulted in the establishment of the Taipei Children's Mental Health Centre in 1955.³

The preparatory work began in 1952 when the Children's Clinic was set up in the Department of Neurology and Psychiatry; its main functions were, firstly, to find out whether it was justified to propose such an establishment and, secondly, to train a corps of mental health workers for children. The training of professional workers remains the major task of the Centre, but considerable contributions have already been made to both the undergraduate and post-graduate training programmes.

A major step towards the goal of introducing mental health into public health was taken in 1959 when a mental health mobile clinic was started. A weekly visit is made by a team of the Taipei Children's Mental Health Centre to the Public Health Training Centre located in a town outside Taipei. The mental health team, consisting of a senior psychiatrist, a psychiatric social worker, a public health/mental health nurse and a psychologist, conduct a conference to discuss cases presented by the staff and trainees; a seminar on major mental health problems encountered in public health work follows the case-conference. It is hoped to expand this activity to the newly-established Institute of Public Health, National Taiwan University, as part of its training programme for health officers.

The effects of such an undertaking are slow to appear and should be carefully weighed. Optimistic perseverance may be

rewarded in the future; in fact this has already occurred in its crudest form after a year's operation, as shown by the enthusiasm expressed by the trainees, the demand for more sessions and also the improved quality of the discussions. A most rewarding experience was the request for a special seminar course made by schoolteachers from the town in which the Public Health Nursing Training Centre is located and prompted by what they heard from the nurses about the course.

Two more projects have been undertaken by the mobile clinic, both in relation to school health, one with a school in Taipei, and the other with five schools at a small town and the adjacent rural area. Weekly seminars are conducted with groups of teachers on the identification of behaviour problems and possible approaches in their management. The emphasis in seminars and conferences is to encourage the participants to search for knowledge and effective tools in dealing with mental health problems rather than to give them "prescriptions," "blue-prints," or "theories." This method has been accepted as most stimulating and with the co-operation of these teachers a survey of the major psychological problems in primary schools is underway.

The National Association for Mental Hygiene has carried the major bulk of mental health education to the public since 1954. The shortage of manpower in mental health has again limited the scope of its work, but the initial efforts in reaching the teachers and college students, and the intellectuals of the community through seminars and lectures have obtained favourable responses. The publication of a series of mental health booklets and the mental health bulletin, in collaboration with the Taipei Children's Mental Health Centre, has succeeded in creating a ring of intellectual supporters in the community.

THE ROLE OF RESEARCH

At the start of the mental health planning it was the desire to assess mental health needs and to understand the resources in the community which led to the census surveys of mental disorder of the three communities. Their results and findings have provided the basis and guide lines for the

³ This Centre, located next to the Department of Neurology and Psychiatry of the University Hospital, is a joint project of the National Taiwan University and the provincial Government Public Health Administration. Dr. H. G. Gundry, WHO Consultant, helped in the planning of the Centre, and ICA donated the building which is presently adding a ward to accommodate 10 children.

ensuing developments in psychiatric education and community mental health programmes. The pragmatic approach which coloured the first phase of the introduction of psychiatry to Taiwan—initially it was manifested in the seeking of precise information by means of surveys—was further strengthened by the very success of the programme which emerged from these surveys. This orientation also permeated not only the clinical activities but the planning of further research programmes as well. Given the shortage of trained research personnel of any sort, the attempt to proceed through factual investigations has not been an easy task. It should be said that the opportunities for mental health research in Taiwan are exceedingly rich but the accomplishment so far has been embarrassingly minimal.

Some of the major researchers and research plans may be summarized as follows:

1. *Epidemiological Studies of Mental Disorders Among the Mountain Tribes.*—Following the surveys of Chinese communities, 4 tribes of the original Malayo-Polynesian inhabitants of Taiwan were studied between 1949 and 1953. These tribes lived in isolation from the Chinese population as well as from each other, differing in language, habits and levels of cultural development. The 4 tribes represented respectively the most "primitive," the most advanced and two intermediate groups.

The research technique adopted was similar to that used in the previous surveys in order that the findings might be comparable. The purpose of this research project was to find out whether the manifestations and prevalence of mental disorder differ between these tribes and the Chinese or differ among themselves, and if so, how they may be associated with socio-cultural and genetic factors. (The report of this study will be published by Rin in 1961.)

2. *Epidemiological study of high blood pressure.*—An increasing need was felt to examine the common belief that the Chinese had low blood pressure and were free from hypertension; hospital statistics and Government reports on mortality had begun to show the increased gravity of hypertension in the community. The rapid social

change after the influx of mainland Chinese since 1948 led to the postulation of a possible association between the apparent increase of hypertensives and socio-environmental factors. Epidemiological surveys of urban and rural populations were envisaged and the study of 9729 inhabitants over the age of 15 of both sexes living in two districts of Taipei was carried out in 1954.

Census household visits were made to measure the blood pressure as well as to collect the medical and social history of each inhabitant. The data are still in process of analysis and only a part of them has been reported (5, 6). It was clearly observed that though the Chinese had lower mean blood pressures in youth, their blood pressure rose with age and became comparable in middle-age to the occidental pressures. Correlation was found between the rates of hypertensives and upper class, and there was some suggestion that current psychosocial stresses experienced by the upper class may play a part in this.

This research project has not only formed a scientific pursuit but also offered unique opportunities for the development of the mental health programme; the collaboration of the departments of medicine and public health in the research has opened the door for further joint activities which, it is hoped, will result in a readier acceptance of psychiatry as a respectable member of the medical sciences.

3. *Therapeutic Effects of Family Attendance in the Psychiatric Ward.*—Traditionally, most hospitals allowed, on occasions even requested, the presence of a family member with the patient during hospitalization. With the introduction of modern hospital management and nursing, this practice began to fade away, or at least to be regarded as undesirable. The psychiatric ward of the University Hospital has, however, kept this practice up to the present and has started an objective study on its advantages and disadvantages from various angles.

The hypotheses derived from the observations of this practice in the past for this research project are the following:

(a) The presence of a family member should be helpful in the transitional adjustment of the patient to the new environ-

ment of the ward at the time of admission.

(b) The presence of a family member should provide opportunities for closer observation of the family relationship and thus assist in understanding some of the possible etiological inter-personal factors.

(c) The family member in the ward, through contacts with the staff and the other patients and their relatives, may learn about the nature of mental disorder and also the required attitude and may acquire some skill in dealing with the patient.

(d) The process of readjustment to the home environment should be made easier for the patient by the continuity provided by the presence of the family member and the understanding and skill acquired by the family.

The adverse effects of this practice are also being looked into, *e.g.*, the effects of the introduction of the complicated family interaction into the therapeutic situation, in particular to the nursing structure. It would make a great impact on future mental hospital services in Taiwan if this practice proves to have beneficial influences on the therapeutic situation.

4. *Epidemiological Follow-up Surveys of Mental Disorder in Three Communities.*—

This projected study is planned to commence in 1961 *i.e.*, 15 years after the previous surveys, and has two main inter-related purposes: (a) to ascertain the change with time in the prevalence of mental disorders in the communities which have undergone radical changes in terms of industrialization and ethnic composition and (b) to study, with more refined methodology and better trained personnel, the socio-environmental factors that may have a bearing on the occurrence and manifestation of different types of mental disorders. Longitudinal prospective studies of a general population are theoretically the ideal method for ascertaining the true incidence and also the natural history of mental disorder in a community. The immense practical difficulties involved both in terms of financial expenses and manpower, and the technical requirements of maintaining the stability of the population as well as the methodology employed, have led many researchers to refrain from the use of this method. It is felt that a follow-up survey

after a 15 years' interval may yield significant findings closely similar to life span prospective longitudinal studies while minimizing the practical difficulties. For this, Taiwan seems to offer good possibilities: the base line information, obtained 15 years ago, is available; the population, though having undergone considerable change in composition owing to the influx of the mainlanders, is well registered; and the same research team, with added experience, still maintains the same degree of interest in this study as 15 years ago. Some change in the methodology may, and undoubtedly will, take place. It is contemplated that, as well as repeating the census household visits, a 20% random sample may be used for more intensive investigations. The criteria adopted for the census investigation will be the same as used in the previous surveys, but may be slightly modified for the study of the random sample.

This research programme is, it is hoped, to be followed by a series of controlled studies to understand the meaning of the correlations between the differential rates of mental disorder in different sub-groups of the population. And, furthermore, another follow-up study 15 years later is also on the time-table of the research programme.

5. *Study of Child Development.*—Psychiatric work with Chinese children is again a completely new field, and the accumulated clinical experiences and some research data have presented a fund of information which does not easily fit into any of the more or less accepted schools of thought. The situation is made worse owing to the rapidly changing social circumstances which children are usually the first to perceive and respond to.

An example of the difficulties encountered may be taken from a research experience which has several parallels in the past. In the years 1947 and 1948 an attempt was made to establish a standardized intelligence test based on the Binet-Terman test and the Japanese Suzuki modification of the Binet test, the latter because of its cultural closeness to Chinese. After a pilot study of 50 children of different ages, a sample of 1,400 children of 5-12 years was chosen from three different schools, in addition to

a small number under the age of 5 directly from their homes. The investigator used at first Taiwanese dialect with small children and a mixture of Taiwanese dialect and Japanese (because Japanese was the official language until the end of the war) with the schoolchildren. After 6 months he found himself using less and less Japanese and in one year's time the use of Japanese was limited almost entirely to the fifth or sixth grade children. He was most puzzled to observe that, after giving the tests for a year, the facility for expression among schoolchildren was becoming extremely limited; for instance, they were unable to give a detailed description of concrete objects, and there was a poverty of abstract thinking for their age. It was thought at first that this might have been due to sampling bias—more children of poor mentality being tested in this particular period of the investigation, but it became clear, by re-testing some of the earlier subjects, that the enforced use of a new language, Mandarin Chinese, in the school was responsible for this restriction of expression. The scoring of the results obviously did not lend itself to any meaningful interpretation, and the whole project was called off temporarily until new patterns of communication and culture in general had established themselves in the community.

A longitudinal study of children from birth to early adulthood is being contemplated to obtain basic information about the patterns of growth and development. The main areas of investigation will be in the learning process, intellectual development, the patterns of relationship formation, attitudes to authority, and the development of the image of self in relation to the expectation of parents.

Many small pieces of research work have been completed or are in progress. It must be admitted, however, that the data obtained from all these research projects so far have added only very little to the fund of scientific knowledge of human behaviour, normal and abnormal, as compared with the vigorous and untiring efforts put into them. This was expected in view of the complex nature of human behaviour, and also of the limitation of the quantity and quality of our research personnel. Qualified

research personnel in psychiatry is difficult to obtain everywhere and it is particularly so in a place like Taiwan where no such personnel can be found ready-made. To obtain such a person, one must first find a young scientific brain, interest him in psychiatric science, find means for him to support himself throughout his psychiatric training, help him learn research technique through participation with research and then see to it that he takes up an academic career; every step of this process of "production" is vital to the end result. The same applies to the obtaining of non-psychiatric research personnel; acute needs are felt for a social scientist, an epidemiologist or biostatistician, and a geneticist, for the planned research projects. For success, the spirit of research should prevail in the Department and critical thinking pervade all activities. The Department is now fortunate in this respect, though still far from ideal. Four senior psychiatric instructors, one neurologist, one child psychiatrist, one clinical psychologist and one senior social worker are actively interested and engaged in research along with their teaching and clinical work. The effects on the junior staff and students have been quite remarkable.

CONCLUDING REMARKS

The mental health programme in Taiwan has made a modest start. The assistance, material and technical, and encouragement received from colleagues all over the world, through personal contacts or international, bilateral or private agencies, have played an important part in its development. To mention only a few: The American Bureau of Medical Aid to China, the Department of Psychiatry of the Harvard Medical School, the World Health Organization, the United States International Cooperation Administration Mission to China (Taiwan), the World Federation for Mental Health. The support given by the National Taiwan University and the Taiwan Provincial Health Administration has certainly been the key factor in the whole process of evolution. It is hoped that this assistance and goodwill will continue and increase to enable the mental programme to grow, looking forward to a day when it may take its

proper share in the advance of scientific knowledge as well as the welfare of mankind.

LIMITATIONS OF MEDICAL TRADITIONS ON COMMUNITY MENTAL HEALTH PROGRAMS¹

Adolf Meyer, in 1913, in addressing the International Congress of Medicine in London(1), declared :

The characteristic traits of a clinic for mental diseases according to my conception should be, first, service to the patient rather than to an administrative system ; second, elaboration of the study of the diseases rather than of means of wholesale handling of patients ; third, possibilities of following up the studies of nature's experiments beyond the hospital period, and preventive work through extramural efforts outside of the hospital . . . [and further] . . . I consider it of the greatest importance that the clinic may itself be responsible for the mental health work of a fairly well circumscribed unit of population so as to make possible studies of the social situation and of the dynamic factors which lead to the occurrence of mental derangement which must be attacked for purposes of prevention.

His words of a half century ago have much in common with the viewpoints that gave rise to the Columbia-Washington Heights Community Mental Health Project. The Project, now in its third year, has established a local community surrounding the Columbia-Presbyterian Medical Center as a laboratory for long term, intensive studies of mental health procedures, therapy and epidemiology of mental health by a university Department of Psychiatry and School of Public Health. The project's aims have been to survey and characterize this urban community as a basis for coordinated community mental health studies. The approach is based on the conviction that knowledge of community life and mental health needs, resources and attitudes is essential to the evaluation and

improvement over the years of preventive, therapeutic and rehabilitative services.

In establishing this project, the interest extended beyond the evolution of epidemiologic methods or studies of prevalence, although it was hoped that such would come too in the course of the work. Surveys are available from this country and abroad that provide fairly consistent minimal rates on the prevalence of the psychoses in a population, in contrast to almost complete absence of figures on incidence. Existent reports on prevalence with respect to the psychoneuroses and personality disturbances, however, reveal wide discrepancies ranging from estimates derived by house surveys, such as that of the Eastern Health District(2) in Baltimore some years ago, to reports from the Rennie studies of Midtown (3, 4), and the Leighton studies of Stirling County(5, 6). The sources of these discrepancies call for explanations that demand more sophisticated epidemiologic methods than are now available in the reporting systems developed in the field of psychiatry.

The vexing problems of our specialty which give rise to part of these discrepancies include the lack of uniform definitions for mental illness and mental health, insufficient data with which to examine and differentiate changes brought about by either the environment or treatment, and inadequately developed techniques for needed data-collection. Without the solution of these problems and the accumulation of sound information, it remains dubious that assessment of change through therapy can be effectively estimated. Thus, how can changes in patients be assessed without studying their social adaptation before, during and after treatment over periods of time? Need we not inquire into the epidemic effect of the patient's illness in his community? (The significance of the last question is exemplified by such findings as that 10% of the children seen in the Domestic Relations

¹ Read, at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² From the Department of Psychiatry and the School of Public Health and Administrative Medicine, Columbia University, New York City.

Court of New York for problems of delinquency have one or both parents schizophrenic and that many of these parents have been in a mental hospital or in psychiatric treatment(7)).

The Columbia-Washington Heights Community Mental Health Project, grew out of concern with such questions. Its inception coincided with organizational changes in both the Department of Psychiatry and the School of Public Health and Administrative Medicine, brought about in part by the conviction that facilities and personnel of each should be rearranged in order to bear directly upon the service functions needed in the community and ultimately upon the training and research activities of both departments. Thus, the united energies of both departments might be turned to a series of systematic and intensive studies of various therapeutic techniques or mental health measures which would be examined against a known background of mental disturbance within a discrete population group and in the light of knowledge of the socio-cultural conditions in the area.

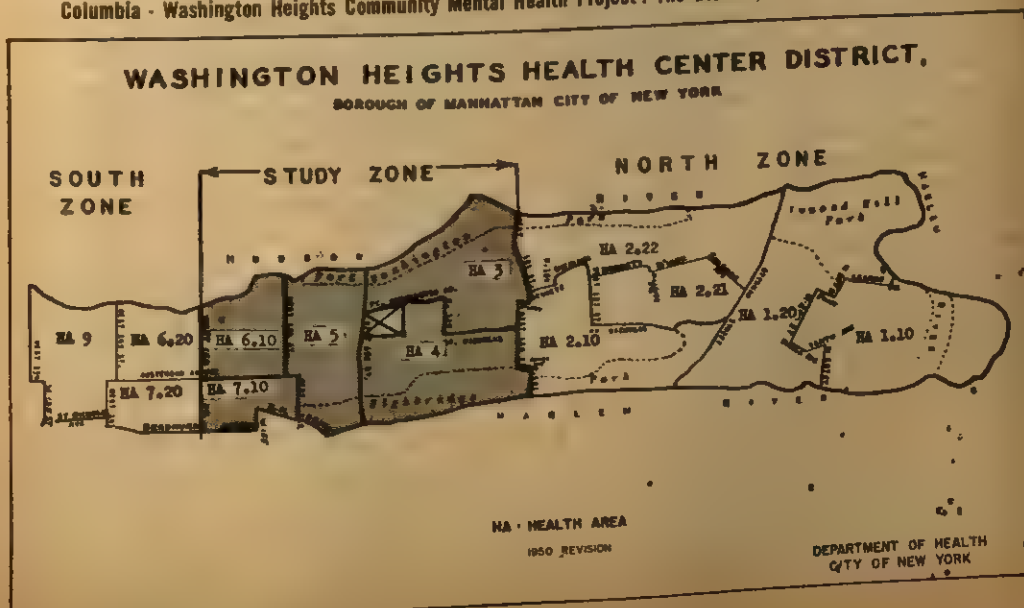

A small basic interprofessional staff has collected and analyzed demographic, sociological and historical data, and established a register of patients in the area which so far includes about 7,000 individuals. A master sampling study of 6,000 households is in

process which will enable the finding of patients not known to the medical profession or community agencies. Investigation is under way of community attitudes to mental health and illness and identification of potential leaders for community mental health programs. The project's staff has been drawn from the fields of psychiatry, public health, social psychology and psychiatric social work, with intermittent and part-time staff from biostatistics, political science and anthropology.³

The Washington Heights Health District has a population of approximately 281,000. Although this entire District is in the area of Project interest (in broad terms), a "Study Zone" has been demarcated within it as a unit of more manageable size for intensive study (see map). The "Study Zone," which immediately surrounds the Medical Center, contains a population of approximately 108,000, of diverse ethnic composition. The "Study Zone" cuts through two of the three traditional communities of the Washington Heights Health District and

³ Continuous assistance has been available from the research, teaching and clinical personnel at the Medical Center; we are especially indebted to Drs. Jack Elinson and Ernest Gruenberg for their sustained and close consultation. An advisory planning group from within the University has also provided valuable counsel.

Columbia - Washington Heights Community Mental Health Project: The District, Zones and Health Areas

is not a community in the customary sense of the word; that is, a collection of people with mutual interests and contacts. Most of the area is residential with supporting shopping centers. The population of the southern area (Hamilton Grange), is predominantly Negro and Puerto Rican. The mid-area (Washington Heights) radiates out from a trade center, with some of its leadership living outside the area. Its population is mainly Jewish and second generation Irish Catholic, with some whose background is Puerto Rican, or of Greek, Italian or other nationality. The population of the northern area (Inwood), most recently developed, is about evenly divided between Jews and mainly Irish descent Catholics, with a few Protestants, the majority of German background. Lower middle and working class groups are more prevalent than middle and upper-middle class groups for the area as a whole, in which a wide range of economic circumstances are found.

The demographic data point up a number of conditions conducive to stress. For instance, the population of the southern area, almost completely Negro and Puerto Rican, pays a median rent equivalent to that of the populations in the northern and middle areas for housing that is the most dilapidated. However, these Negro and Puerto Ricans received a lower income per capita, although their educational level closely approaches that of the other two population groups. Population shifts within the region, particularly from Negro and Puerto Rican expansion northwards, contribute to stress conditions in neighborhoods that are undergoing rapid changes in ethnic and racial composition. Another stress situation within the Study Zone provides a ready-made experimental opportunity with respect to variations in rates and kinds of emotional stress reactions. This situation stems from the enforced relocation of 1,800 families due to construction of new approaches to the George Washington Bridge. Study of relationships between psychosocial stress and psychiatric symptomology is relevant to planning community mental health programs. Such relationships were not taken into account in the past when many of the prevailing practices were established.

In the health district 189 institutions have

been identified that have some potential or actual relation to mental health services. These include health, educational and welfare facilities but not the 335 or so local physicians, with whom we are also attempting to establish cooperative contact. Within the Medical Center itself, an imposing list of specialized personnel and facilities give service of various kinds. In spite of this richness of resources, it has become clear that their effectiveness in operation is impeded by several factors. Traditional isolation of the various groups from each other often has prevented the flexible movement of patients from one unit to another in terms of their treatment needs. Such isolation has hindered the use of consultative services even when these are clinically indicated and available.

Existing personnel and psychiatric facilities are so organized that they often fail to serve local community mental health needs. For example, when the project started, only 2% of the annual admissions to the specialized psychiatric hospital came from the local community. All other patients requiring psychiatric hospitalization, whether from the other medical center units or elsewhere, had to seek aid at the city receiving hospital 150 city blocks away. Thus, the project study of organizational structure led to revised psychiatric admission policy in the medical center psychiatric units which has led to provision of service for a significantly increased proportion of the mentally ill from the local community. This in turn provided important leads for further fact-finding and programming at the community level. In this instance, as in many others, the collection of data and the patterning of services have had reciprocal influence on each other. The traditional design of epidemiologic research as linear sequence from data-gathering to service-design is seen as limiting to community mental health programming as compared with a circular process with reciprocal feed-back.

In general, work in the project has confirmed the early assumption that the data-gathering process itself constituted a community mental health activity, both in terms of adding a new and contributing unit and also in identifying obstacles and resistances to needed improvements which require

problem-solving. It was predicted that involvement of medical and nonmedical community leadership in data-gathering would help to stimulate the much needed assumption of responsibility and accountability by the community for care of its emotionally disturbed members. Interchanges for seeking information have the potential for increasing the recognition of mental illness and emotional maladjustment in the community as well as cooperation, communication and collaboration with other community groups for its alleviation. For example, some pilot interviews were undertaken with private practitioners in the area as a step towards completing the count of psychiatric patients in the Study Zone. Although these interviews centered on devising acceptable questionnaire forms, they also provided channels of communication in which the physicians' feelings about the local medical center, including complaints, were aired and explored, misunderstandings clarified, and constructive criticisms provided cues for needed improvement in medical center services. An appropriate referral by a previously hostile physician to Vanderbilt Clinic following such an interview illustrates how better communication achieved in data-gathering improves collaborative service to patients.

On the other hand, some of the barriers to data-collection which have been encountered, impede ascertaining the extent and nature of need which is necessary for planning, organizing and coordinating of services. These barriers often have been found to be due to well entrenched medical traditions that are inappropriate now for advances in modern psychiatry. They may be thought of as outmoded. Such barriers include certain recording practices as well as problems related to confidentiality. With respect to recording: the information that is recorded or fails to be recorded by psychiatric facilities, general hospitals and various agencies is determined mainly by what is deemed most useful and important (aside from such non-clinical factors as budget and staff pressures). The inpatient philosophy that still puts low value on coordination between units for pre- and post-hospital care and their preventive and rehabilitative potentials leads many inpatient psychiatric

facilities to neglect such data in their records. In general hospitals, traditionally lower prestige accorded to outpatient departments contributes to relatively lax record room procedures for outpatient charts. Since the greatest number of psychiatric patients (and also those seen at the most crucial phases of their disorders) are outpatients, such laxity limits both the research and service uses of these records. Furthermore, due to the tradition whereby somatic illness continues to hold higher scientific and moral status than psychiatric disorders, considerable reluctance was found in this study by general hospitals' record rooms to include recordings of primary or secondary psychiatric diagnoses even when such had been made on patients seen on medical and surgical wards. In many psychiatric, social and educational settings, the uneven and inadequate recording of relevant social and psychological data, seems due to traditional narrowness of professional focus by the respective disciplines established before the development and acceptance of such concepts as total personality and comprehensive psychiatry.

Another tradition-linked source of error arises from trying to circumvent anachronistic legislative and administrative policies through the choice of diagnosis to be recorded. Although this may be motivated by well-intentioned therapeutic expediency, such diagnostic manipulation creates obvious confusions and dangers and is scientifically untenable. It would seem far preferable to apply current psychiatric insight through appropriate change-inducing techniques, including community action, towards revising those long-standing policies and laws which obstruct the carrying out of clinically indicated case disposition.

As regards the maintenance of confidentiality of records, the authors are committed professionally to the ethical principles of protecting patients from the abuse of personal information they have given in confidence to qualified persons. It has been found, however, that traditional reluctance impedes release of such psychiatric information as names, addresses and diagnoses even when rigorous legal and research safeguards are in force. Indiscriminate withholding of such information seriously hampers the pooling of data essential for planning, utilization

and evaluation of community services. In determining the patient population of the area, the project benefited by valuable co-operation with the statistical office of the Department of Mental Hygiene, the New York City Community Mental Health Board, Manhattan After-Care Clinic, and the record room and various special units of the Presbyterian Hospital of New York. Initial efforts to obtain data from the smaller hospitals in the area and from various governmental departments have been hampered by fears of law suits, voiding of liability insurance or increase in the rates of such insurance. Yet the Medical Practices Act of the State of New York specifically allows release of such information for research purposes. The project staff has met with administrators of hospitals serving Washington Heights residents, representatives of the Board of Education and heads of private and public agencies, to explain and reassure them as to our scientific aims and safeguards with respect to needed data. Such conferences also have served to improve communication towards needed collaborators, coordination in the treatment of the area's patients.

Entrenched patterns of autonomy and isolation on the part of hospitals, clinics and agencies with respect to each other contribute to an antitherapeutic fractionation of patient care. Many longstanding organizational patterns which derive from overlapping governmental units and systems of patient referral disregard continuity of care. The splintering of services between the local voluntary hospitals and clinics, the city hospital, the state hospitals and after-care clinics and agencies, fails to allow the establish-

ment of the major psychodynamic factor needed for the treatment of many psychiatric patients; i.e., a sustained and consistent therapeutic contact with a single physician or his representative institution, who is also knowledgeable about the patient's family and community environment. It was found, for example, that 33 different hospitals and schools took care of 636 patients from the Study Zone population of 108,000 in one year and also that patients from this small metropolitan area for the most part were distributed among nine State hospitals scattered over an area extending to a peripheral distance of eighty miles (Table 1). Hospitalization at long distances from home markedly reduces helpful contacts between the patient and his local community. Visits by relatives and social workers become difficult and the hospital staff must rely on transmitted information from a multitude of distant agencies which cannot provide the intimate type of professional or family contact so important for the patient's posthospital readjustment in the community.

Since it has been repeatedly demonstrated that the readjustment of many hospitalized patients is improved by working concomitantly with their families, the extent to which this has not yet been translated into practice generally, exemplifies the many lags between existent clinical understanding of individual patients and its application at the collective level of patient care, where the relative inflexibility of tradition is greater. Psychological mechanisms of isolation and compartmentalizing on the part of the general public and the mental health professions would seem to contribute to this inertia for maintaining the procedural

TABLE 1
Washington Heights Residents Admitted to Records of

status-quo for patients *en masse*, which curtails their benefits from advances in psychiatry. (As referred to above, the project is investigating attitudes towards community mental health programs; the results will be reported separately).

Psychiatric services in general hospitals, especially when closely related to teaching and research activities, are key components of the community's psychiatric resources. Yet, certain traditions that shape many features of general hospital organizational structure, which developed in relation to physical care, are detrimental to psychiatric practice and may seriously limit effective psychiatric treatment in this propitious setting. Traditionally, for example, inpatient services which care for the physically sicker and more complicated patients, receive for their staff the most highly qualified physicians and provide for these men higher professional prestige than outpatient departments where less experienced physicians are usually assigned. But for community oriented psychiatry, the outpatient department demands primary importance and requires high levels of professional expertness.

In studying the general admission process to the outpatient department of the local medical center (a general hospital), it was found that of the 450 new patients registering daily, 80 were seen for only the single brief visit and returned home. A follow-up study of these patients has revealed that a high proportion suffered from some form of psychiatric illness which went undetected or ignored during the clinic admission procedure.

In thinking of the process of acceptance of patients for outpatient treatment in the large teaching centers, it appears that the traditional assignment of a medical or surgical intern with minimal psychiatric background as hospital admissions officer results often in his inability to recognize psychiatric problems as such, to make adequate referrals, or to manage the problem himself. For the most part, those patients that he does refer to the psychiatric clinic have gross disturbances while the subtle indications of early illness are missed. In actuality, initial screening and early disposition requires highly specialized skill and, of course, has crucial relevance to early case finding and

appropriate use of existing facilities. Thus, the assignment of the most junior physicians as admitting and emergency officers, a tradition with some logical basis in relation to physical illness, proves detrimental with respect to care of psychiatric illness. (The intern serving as admitting officer for the physically sick is apt to refer problems of serious nature into the hospital rather than assume responsibility for their referral or care, thereby providing a factor of safety for such a patient.)

In the larger teaching centers, also, admitting interns are influenced by their conception of "the good case," as indicated to them by their senior inpatient instructors. Such interns, however, are often uninstructed relative to the personality disorders and unable to estimate the ultimate consequences to the patient of how they refer or fail to refer. Many psychiatric cases are seen as a nuisance unless critically upset, to be sent home or referred back to the local physician or hospital whose inability to provide appropriate and needed treatment caused the patient to seek admission to the medical center in the first place.⁴

Comparable shortcomings were found through a follow-up study of 38 children who had been referred for psychological testing by the pediatric service. The care that had been given was evaluated as satisfactory in but 7 of the 38 cases. Only 10 out of 32 recommendations for 23 of these cases had been carried out. Traditional patterns of organization, rotation of responsibility and poor interdepartmental communication within the medical center accounted for these findings in part, while others seemed due to deficiencies of collaboration between the hospital and the schools and agencies in the community. There is basis to assume that those kinds of problems are typical for other large urban hospitals and clinics.

Four hundred and sixty-nine patients from Washington Heights were admitted to the psychiatric service at Bellevue Hospital (the city receiving hospital) during one

⁴ This is not to be misconstrued as unjust criticism of interns, who are themselves caught up in these problems. Documentation will be made available through a separate report of our follow-up studies of patients who were turned away during the admission process.

year. Of these, about 40% were transferred to State hospitals. By study of the records of the remaining 60%, the evidence seems to point to serious gaps in the local network of facilities, as well as to weaknesses in community patterns of initial screening, referral practices and discharge planning. For many of these patients, admission to city hospital reflects poor clinical use of more suitable community alternatives. Not only may this inflict damaging trauma, but reduce ultimate treatability. For others in this group of patients, the Bellevue admission occurred because more appropriate community resources were lacking. Thus, about 43% of the cases returned to the community were associated with alcoholic intoxication. Facilities for the care of addictive personalities, whether associated with the use of alcohol or narcotics, are quite inadequate. This inadequacy has been perpetuated by traditional attitudes of moral condemnation towards the addicted; even the professional community has shared these prevailing attitudes, to the detriment of its clinical objectivity.

SUMMARY

A series of entrenched medical traditions has been recognized as obstructive for the development of effective mental health practices and the on-going assessments of patient care. Traditional patterns of isolation within and between medical and non-medical facilities of the community's resources contribute to maintenance of weak patterns of coordination, communication and fulfillment of responsibility with consequent antitherapeutic fractionation, discontinuity and inflexibility of services. Some organizational traditions in state hospital systems, such as distance from the patient's home and poor liaison with other community facilities, impede postdischarge readjustment. In general hospitals the old tradition of placing those with greater professional experience on inpatient services which led to enhancement of their prestige is detrimental to the growth and strengthening of the admissions office and the outpatient departments which have major importance for community mental health programs, and require high levels of pro-

fessional expertness. These factors are reflected in traditional organizational features of general hospitals, and influence staffing patterns and admissions procedures and policies that are now adverse to early detection and treatment of psychiatric illness. They lead to incomplete and inaccurate recording of psychiatric diagnoses and minimal attention to outpatient charts. By identifying these traditions and the obstacles they raise, it is hoped that appropriate revisions come about which will lead to more effective patient care.

DISCUSSION

CURTIS G. SOUTHARD, M.D. (Bethesda, Md.).—This Project is pilot and exploratory in nature. Its goals incorporate many of the new and progressive concepts about community care and treatment of the mentally ill. Mental health services are combined with training and research in a community setting, a program which ought to be more common throughout the country. The authors give convincing evidence of the reciprocal feedback between data gathering and service design which is vital to the development of program. This should remind us that data gathering should not be considered a nuisance but as a continuing part of the effort necessary to effect change to meet community needs. Of course, budget and staff must be provided to make this possible.

The Project seems to be focused primarily upon the mentally ill. Preventive and promotional services, public health activities which reach the mass of the population, the healthy

as well as the sick, are lacking. However, mention was made of social and economic pressures in the community which might cause mental illness. Undoubtedly information and communication provided by the program as presently focused would be of great value for developing a preventive program later. If this is done, I believe that a completely new set of reference points in the community will be needed and that professional staff other than clinicians will be active participants.

From the administrative, organizational point of view, if the project is to be regarded as a demonstration of community mental health programming for other communities, many public health personnel would raise questions about locating the central core of a community mental health program in a hospital.

Also I'm not sure to what extent a neighborhood or a part of a neighborhood in a large city can be considered as a "community." In a place like New York City, which is overwhelming in its size and complexity, perhaps the neighborhood approach may be compared to the attempts to divide a large mental hospital into several smaller, quasi-independent hospitals of manageable size.

The Project experience thus far indicates that certain traditions limit mental health programs. I wish the authors had had more time so that the second section of the paper on the limitations of medical traditions could have been discussed in more detail. Each tradition by itself could form the basis for a separate paper. In relation to the brief statement on confidentiality, for example, I would have liked to have the following points reviewed: What is the history of the development of this tradition? What purposes does it serve? How seriously does this tradition interfere with research or the planning of community health services? To what extent is the experience in the Washington Heights area typical of other parts of the country? If the tradition should be changed, what changes are needed?

The tradition of maintaining confidentiality seems to have been a significant hinderance to the study and probably will be less amenable to change than other traditions. Perhaps the tradition of maintaining confidentiality need not be changed but a better understanding of the permissible use of records should be encouraged.

To my mind the most significant obstacles described were the isolation, lack of coordination and communication in the community's mental health facilities. This is a nationwide and not just a medical problem. It is a basic

problem of the organizations of our society which results in part from the increasing complexity and specialization of our activities, from urbanization, and from the massive growth of our population.

The admission service for hospitals as it affects psychiatric referrals is emphasized in this paper. I think some considerations were omitted which could lead to erroneous conclusions on this subject. Having an intern as admission officer was properly referred to as a problem and I would agree that it may be a costly procedure for both patient and hospital. However, data were cited to indicate that the intern is more accurate in his somatic diagnoses and referrals than in psychiatric cases. Granted that the intern may not have had sufficient psychiatric training and experience, I doubt if the problem results entirely from these lacks. The intern may know that the outpatient department and hospital are crowded and only the seriously mentally ill would receive attention. He may be very well aware that a psychiatric referral involves a lot more than sending a note to E.N.T. that a patient needs care for a cinder in his eye. Also there is the matter of acceptance of the illness and of the referral by the patient and his family plus the feelings of the intern about directing patients to a psychiatrist, which is difficult even for many experienced physicians.

The lack of proper facilities for early treatment and follow-up of cases treated at Bellevue appears to illustrate a critical problem which is common throughout the country. I am optimistic that this Project will go a long way towards solving it in the Washington Heights area of New York City.

Despite the limitations of medical traditions, the authors appear to have made marked progress in putting their program in operation. Examples were given which indicate that medical staff can change. We could speculate that change will take place readily if the administrative machinery will allow it and if personnel are kept abreast of new findings.

In closing, I would like to point out that the authors have tackled what many health authorities believe is the biggest problem facing psychiatry and public health today; that is developing adequate facilities, properly utilized, to carry out a comprehensive mental health program for prevention and treatment of mental illness. There are only a few projects of this nature in this country—there should be more. I congratulate the authors on the fine beginning they have made and I am sure that program directors throughout the country will follow their work closely!

EFFECTS OF CHEMICAL STIMULATION TO DISCRETE BRAIN AREAS^{1, 2}

ROBERT G. HEATH, M.D., AND FLORIS de BALBIAN VERSTER, Ph.D.^{3, 4}

In this report, we describe some of our findings concerning the effects of stimulation, by a number of chemicals, to discrete brain regions, and the techniques which we have developed for the procedure. Data to be presented were obtained from studies with cats, monkeys and human subjects. Most of the studies were conducted with monkeys; brief references will be made to pertinent data from our cat studies. Human data will be included in regard to subjective reporting immediately following the chemical stimulation where they will clarify some of the objective findings with monkeys. We plan to report our human data in detail after sufficient time has elapsed for adequate follow-up studies.

This method of investigation and treatment has evolved as an extension of our subcortical electrode studies and, in each instance, has been employed in conjunction with chronically implanted cortical and subcortical electrodes.

MATERIAL AND METHOD

Seventeen (17) Rhesus monkeys were employed in this study. Techniques were improved throughout the period of the study. The chemicals were introduced into precise, intracerebral regions through modified hypodermic needles and through specially constructed perfusion cannulas (to be described) for intracerebral stimulation. The modified stereotaxic apparatus was employed with air encephalography for the placement of the electrodes and the needles or cannulas. (A minor modification of our implantation technique for chronic electrodes⁽¹⁾ is necessary for cannula implanta-

tion.) Each needle or cannula was implanted through a small trephine hole and fixed at the bone. Quick-hardening dental cement was used to fix the needles in position and a special plastic plug was designed to fix the perfusion cannula. In our earlier studies with animals (15 cats, 12 monkeys), the needles were placed in widely dispersed nuclear masses; in the later animal studies (2 cats, 5 monkeys), placements were into the septal region and the hippocampus because these areas were the most sensitive to the chemicals employed. In the 2 human subjects (one, a post-encephalitic brain syndrome; the other, a chronic, catatonic schizophrenic), cannulas were implanted into the septal region bilaterally. In addition, cannulas were implanted in both hippocampal regions of one human subject, and in one hippocampal region in the other human subject (Figure 1). In the animals and in the human subjects, electrodes were implanted in specific, subcortical nuclear regions, and over the cortex with the technique previously described⁽¹⁾.

No animal was employed in the study until a minimum of 7 days had elapsed following implantation of the electrodes and cannulas or needles. During the first 7 days following operation, artifacts consequent to the surgical procedure are present. Each animal was used on a number of occasions. At the conclusion of the study, the valves or needles were checked for patency and localization with a small amount of opaque media (Urokon Sodium Sterile Solution 70%, Mallinckrodt). The animal was then sacrificed, and the brain sectioned and stained with Kluver's Combined Stain. The sites of electrode implantation were ascertained, and the sites of injection examined for possible cellular damage.

In 3 instances, when the modified hypodermic needles were employed, there were complicating abscesses around one of the needle tracts. All data obtained from these animals were discarded from the study.

A Perfusion Cannula for Intracerebral Microinjections: This device is adapted for use with the stereotaxic instrument and consists of a valve to which is attached a length of polyethylene tubing. Our procedure for implanting subcortical electrodes(1), with minor modifications, is employed for placing the subcortical valves. This procedure eliminates the shortcomings of our earlier techniques and meets the following essential criteria for an effective method.

1. **Localization.** It must be possible to inject exactly into a predetermined target area. Fixation methods must be such that the device remains accurately in place for prolonged periods.

2. **Minimal destruction of brain tissue.** The device should be of relatively small diameter. It also should be flexible to eliminate damage from pulsation of the brain.

3. **Asepsis.** The device must be designed and implanted in a manner to eliminate pathways for the entry of bacteria into the brain.

4. **Flushing.** In order that cross-contamination of one compound with another does not occur, the device must provide a method of flushing without entry of the flushed material into the brain.

5. **Volumetric accuracy.** Provision must be made for delivery of accurate volume at the tip of the cannula.

Details of the construction of the perfusion cannula have been presented elsewhere (2). Basically, the cannula consists of a small polyethylene tube inside of a larger tube (#PE-10 and #PE-60) with a reservoir and valve system at the intracerebral

end. The terminal, i.e., intracerebral end, is attached to a specially designed valve. The inner polyethylene tube is the inlet and the larger tube serves as an outlet. After flushing, the outlet tube is clamped, and the injection of a micro amount of fluid then causes the valve to open (Figure 2). The cannula is fixed to the bone by a specially designed Lucite plug. This plug also fixes the intracerebral electrodes into position(2).

The maximum quantity of solution injected into the brain substances, with our earlier techniques employing the needles, was 0.1 ml. With the development of the perfusion cannula and, thereby, greater control of volumetric accuracy, the quantity of solution injected did not exceed 0.02 ml., and, generally, ranged between 0.01 ml. and 0.02 ml.

A number of basic studies were carried out with animals to check the various aspects of this technique. To ascertain the period of time that the injected compounds remained in the brain, radioisotopic histamine was injected through the chronically implanted needles into the brains of cats. The animals were sacrificed at regular intervals following injection and the brains homogenized and analyzed for isotope content. As shown in Figure 3, the level of the chemical in the brain remained relatively constant for a period of 2 to 3 hours following injection; then, was rapidly eliminated. When the chemical was injected into the ventricle and sub-dural space, it was eliminated rapidly from the brain. We have noted that when histamine, one of the

FIGURE 2

Schematic Diagram Illustrating the Mechanism of Action of the Intracerebral Cannula

chemicals employed in these studies, produced a physiological effect, as indicated by subcortical electrical recordings, the physiological changes persisted for approximately the same length of time as the chemicals remained in the brain, as ascertained by radioisotopic studies.

Studies have been reported(3) to suggest that inorganic compounds, which become incorporated into the tissues when injected into the brain, remain for very prolonged periods, i.e., up to several months. In our studies, we employed only organic compounds which are metabolized and excreted.

RESULTS

The chemicals which were tested in the monkeys are listed in Table 1. The com-

TABLE 1
List of Compounds Given by Intracerebral Injections
(Active Compounds are Capitalized)

Acetylcholine	Manganous chloride
ATROPINE	IPROMIAZID
d-Amphetamine	Isoniazid
Diamine oxidase	PHENOBARBITAL
EPINEPHRINE	Potassium
Gamma-amino-butyric acid	Saline
HISTAMINE	Sodium chloride

d-LYSERGIC ACID DIETHYLAMIDE	

pounds which induced a change in behavior or in the electrical recordings are shown in capital letters. A significant observation,

FIGURE 3

Graph Depicting the Rate of Disappearance of Radioactive Histamine from Cat Brain with Injections Into Caudate Nucleus, Ventricle, and Sub-dural Space

in reviewing the over-all chart, is that so few compounds with established neurochemical action peripherally induced changes in recordings or behavior.

Unquestionable behavioral changes which, invariably, were associated with significant alterations in recordings, appeared only when chemicals were injected into the septal region and hippocampus. No significant alterations in behavior were induced by injection into other subcortical nuclear masses which included the caudate nucleus, the hypothalamus, and the putamen. For this reason, in our later studies, we confined the placement of our limited number of cannulas to the septal region and the hippocampus. In a few instances, alterations in recordings were definite with no observable behavioral changes in the monkeys.

Regional Localization of Responses to Chemical Stimulation: Our studies suggested that the regions where chemical stimulation induced changes in behavior and recordings were well circumscribed. Injection into a region only 2 or 3 millimeters removed from a very active site often induced no change. The cross-section of the brain of a cat employed in one study illustrates this phenomenon (Figure 4); this was an unfriendly, uncooperative cat. Septal extract,⁵ when injected into the left septal region at the site indicated in Figure 4, immediately induced a mild catatonic picture followed by purring and placidity in the animal which persisted for 30 minutes. Injection of the same amount

⁵ This extract consisted of bovine septal tissues digested with commercial trypsin.

of the same septal extract into the right hemisphere at a site 2 millimeters lateral to the septal region, as indicated, did not induce any observable behavioral change. In this animal, the experiment was repeated on 32 occasions on different days with the same result each time.

Effectiveness of Different Compounds : The 3 compounds, in the group we tested, which induced the most intense changes were septal extract, atropine, and histamine (see Table 2). The injection of septal extract and atropine almost invariably induced changes. The response to histamine was less consistent: on some occasions, it was followed by marked change; on other occasions, by minimal change; on still other occasions, by no change. Variable

responses occurred with the injection of epinephrine, iproniazid, d-LSD, and levarterenol (see Table 3).

With septal extract, behavioral changes were most marked with injections into the septal region, and somewhat less intense with stimulation to the hippocampus. The monkeys became more placid, stopped biting and scratching when prodded, and seemed generally more content. Profound alterations occurred in electrical recordings (Figure 5), best characterized as seizural activity focal in nature and restricted to the septal region and hippocampus. This activity persisted for long periods, the most extreme being 3 days of continuous paroxysmal activity followed by intermittent activity of this type for 6 weeks. The short-

FIGURE 6

Subcortical and Cortical Recordings from Patient, R.B., Before and Following the Injection of Epinephrine into the Hippocampus

est duration of this activity, following injection of active septal extract, was a period of several hours.

Very little information is available as yet as to the chemical composition and stability of the septal extracts. Different methods have been employed in preparing the extracts and there is variability in their chemical composition and in their activity with our testing. The extract contains a large number of amino acids, peptides, and variable, but quite high, quantities of electrolytes. After measuring the electrolytes in the septal extract, we administered, as a control, a triple concentration of sodium and potassium chloride with no effect. Gamma-amino-butyric acid is a consistent constituent of the extract and has no effect when injected intracerebrally (see Table 1). The extracts gradually lose activity over a period of several months, as determined by this test, even when held in the lyophilized state under refrigeration.

Responses to histamine are quite variable, not only from one animal to the next, but with injections on different days in the same animal. Behavioral manifestations range from no change through a mild reduction in the level of awareness to a full-blown catatonic picture. On some occasions, there is a mild increase in beta rhythm on the recording. With a reduction in the level of awareness (clinical observation), there usually was some evidence of slowing in the septal and hippocampal leads. The full-blown, catatonic picture was associated with profound slowing in the septal region and the hippocampus with frequent spikes of the type we have described as appearing in recordings from these regions in our psychotic, schizophrenic patients. Recording and behavioral effects persisted for 1 to 3 hours.

The injection of atropine consistently has induced clear-cut alterations in recordings. Characteristically, there appears, at intervals of 2 to 4 seconds, a broad base slow spike in the recordings from the tissue into which the chemical was injected. Behavioral changes with atropine have been minimal. In the animals, there was nothing definite—only a suggested change towards increased relaxation. Recording changes following injection with atropine persisted

in the animals for 1 to 3 hours. In the human patient with brain damage, very little alteration in behavior was noted with the injection of atropine. Perhaps the subject was slightly more relaxed during the $1\frac{1}{2}$ hour period that spikes, induced by the injection, were present in the recording. The schizophrenic patient developed an increase in spiking in the septal region and the hippocampus. Occasionally, spikes were present in her pre-injection baseline (although sharper, and of higher amplitude), but they increased markedly in frequency following the injection of atropine. She became more agitated and the picture changed from one of retarded catatonic to one of agitation.

The second group of compounds, i.e., those that produced minimal and variable effects which were not consistently repeatable, included epinephrine, d-LSD, iproniazid, and levarterenol. Following injection of these compounds, the animals appeared slightly more relaxed, tended to become more drowsy, and the recordings were commensurate with the behavioral changes in that they showed increased production of alpha activity and background synchronous activity of a sleep pattern. Changes in recordings in the patient with brain damage, with the introduction of these compounds, were minimal, as with the monkeys. In the catatonic, schizophrenic patient, the high amplitude pattern of spindling appeared in the hippocampus, as shown in Figure 6, after the injection of 20 gamma of epinephrine into that region. The patient was relaxed, calm, and more cooperative.

DISCUSSION

The intracerebral chemical stimulation is an extension of our depth electrode studies. With the technique we developed for implanting electrodes in animals, and later in patients, we collected data demonstrating correlations between electrical activity of the brain and alterations in behavior. Significant recordings, correlating with the behavioral changes, were obtained from the septal region and hippocampus. Changing levels of psychological awareness, whether spontaneous or induced by the administration of exogenous substances (viz., pharmacological compounds), or by the

manipulation of interpersonal relationships, were accompanied by predictable recording changes from these regions. These data have been the subject of numerous reports from our laboratories since 1950(4-7). The recording data, along with consideration of the effects of ablation and stimulation of specific subcortical regions in animals, provided the basis for our assumption that electrical stimulation to the septal region might be of therapeutic value in schizophrenic patients.

Since 1950, we have chronically implanted electrodes on 55 occasions in human subjects. All patients received stimulation to discrete, subcortical nuclear masses(7). Many different parameters of electrical stimulation have been employed. The most striking benefits in behavior were achieved with stimulation to the septal region. In 1952(4), we described the pleasure responses or "good feelings" which patients reported with stimulation to this region, accompanied by objective changes in the direction of immediate alerting. Although this desirable, immediate response was consistent, we have been disappointed in the long-term effects of this procedure. In our studies with humans, we have not been able to induce this pleasure-yielding response by stimulating other subcortical regions. In response to stimulation to other regions, patients either have reported no change or have complained of varying degrees of discomfort. Several other investigators(8, 9, 10) subsequently described behavioral effects with stimulation to discrete brain regions in animals. Descriptions of pleasure response in animals to stimulation of areas, in addition to the septal region, are not in keeping with our experience with human subjects.

The therapeutic limitation of electrical stimulation led us to explore the possibilities of intracerebral chemical stimulation in the hope that the widened parameters of stimulation might prove more effective therapeutically in the treatment of behavioral disorders. Technical improvements ultimately made it possible to extend these studies to human patients.

The interesting and dramatic response in monkeys following stimulation with septal extract and histamine are, in our opinion,

of considerable significance. The septal extract elicits these reactions only when injected into the septal region, suggesting that specific receptor sites exist there. The activity of histamine, as related to stress response, at the base of the brain and, particularly, in the basal-olfactory regions, has been the subject of a number of scientific papers. Harris(11) has determined that levels of histamine at the basal regions of the brain are higher than elsewhere in the brain, and that injection of histamine into the third ventricle of the rabbit is followed by a stress response. He has postulated that the release of histamine in the region of the hypothalamus might be of importance in the stress response. Sawyer(12) demonstrated that the resultant stress response with the injection of histamine into the third ventricle is associated with high amplitude spindling on the electroencephalographic recordings from the septal region. The stress response was eliminated with a lesion in the septal region. Earlier studies from our laboratories demonstrated a relationship between activity of the septal region and stress, as measured by urinary 17-ketosteroids and eosinophile response, to electrical stimulation(13, 14). In another paper(15), we presented data showing that diamine oxidase levels were higher in these rostral, basal regions of the brain than in the cortex or in the brain stem. These studies have led us to speculate that the histamine and, as yet, incompletely identified enzymes for metabolizing this compound, might exist in high quantity in the septal region and that the interaction between them could be of considerable importance as the chemical substrate for the physiological activity of this key brain region with associated behavioral fluctuations.

SUMMARY

A cannula, and a method for its accurate implantation into predetermined brain regions, is described. This technique makes possible the accurate injection of minute quantities of chemicals into specific deep regions of the brain. The behavioral effects and concomitant changes in electrical recordings from subcortical structures induced by the injection of a variety of compounds and brain extracts into selected

brain regions of cats, monkeys, and humans are described. The most consistent and dramatic changes were induced with the injection of bovine septal extract, histamine, and atropine.

DISCUSSION

MAX FINK, M.D. (Glen Oaks, L. I., N. Y.).—Dr. Heath and his co-workers once again present a series of provocative preliminary findings which indicate a willingness to undertake a most difficult and painstaking task and accomplish much in a short time. This report describes a technic for introducing 1/100 to 1/50 cc. solution into discrete brain areas, in animals and man. Certain observations are reported,

including greater behavioral responsivity occurring following injections in specified loci, notably the hippocampus and the septal regions; and the agents found most active in these areas have been atropine, histamine and septal extract. I should like to assess the historical significance of this study as well as raise some technical questions.

The major neurophysiologic studies of the past decade have demonstrated that by the use of depth electrodes, electrical activity not measurable in scalp or surface leads, can be recorded; and that the electrical activity occurs in the various tapped cerebral sites and not in others nearby. Electrical stimulation in various loci elicits different behavioral consequences for different sites and behaviors generally described as "positive or negative" or "rewarding or punishing" can be elicited from loci, only a few millimeters apart. These observations have been repeatedly made in man as well as animals, and represent the latest cartographic analyses of brain function.

Parallel with these neurophysiologic observations, considerable study has gone into the biochemical relations of brain function and behavior. With the renewed interest in psychotropic and hallucinogenic drugs, all clues indicate that alterations in brain function underlie the behavioral changes of these agents.

In the experiments reported here, these 2 streams of experimental neurophysiology are brought together. These preliminary findings are exciting because they show promise that a more physiologic stimulus to the nervous system is being studied. The studies of the behavioral and neurophysiologic interrelations of convulsive therapy and lobotomy, are essentially relationships of massive brain changes. The studies of psychotropic drugs, electrical stimulation, or electrocoagulation are less massive in their effects, but essentially "non-physiologic" in their character. The introduction of metabolites, ordinarily present in the nervous system, to localized areas, may give Dr. Heath and the other neurophysiologists in psychiatric and parkinson disease institute, a more delicate tool upon which to base the much needed neurophysiologic-behavioral correlative studies.

Among the interesting points in this report, I am most struck by the "apparent" differences in behavioral response for the agents tested when administered peripherally or centrally. Like Feldberg's and Sherwood's studies, these drug patterns are puzzling, and tend to suggest that homeostatic chemical balance mechanisms, so clearly demonstrated in various peripheral systems, are active in the brain as well.

This new technique may be helpful in eluci-

dating drug-neurophysiologic-behavioral relationships. But like all new technics, this one raises many questions which must be considered seriously. What is the relation of the osmotic pressure of various solutions, on the cells about the injected site? What is the diffusion rate, and how does volume of solution affect the results? Like some of the earlier studies of electrical stimulation, this technic has promise—but hopefully the technical details will be

worked out better than the parameters of electrical stimulation have been studied—for many of the results now ascribed to brain centers may equally be related to the electrical parameters of the stimulus and not the anatomic locus.

I should like to express my admiration for Dr. Heath's experimental enthusiasm and activity, and I look forward to the continuing biochemical-neurophysiologic relationships which are forthcoming from his laboratory.

SENSORY HABITUATION AND DISCRIMINATION IN THE HUMAN NEONATE¹

WAGNER H. BRIDGER, M.D.²

Our interest in studying the sensory capacity of human neonates stems from two frames of reference—neurophysiology and clinical observations. Both of these approaches are aspects of our main objective which has been a search for psychophysiological phenomena that will distinguish babies one from the other at birth. This search is based on the supposition that so-called basic temperamental differences may influence the reciprocal interaction between mother and infant and thus affect personality development. These differences may also help explain why certain environmental stresses produce severe personality deviations in some individuals, and not in others.

We decided to study sensory capacity because we feel that the techniques that we devised are closely related to clinical observations and also are related to recent important neurophysiological advances. In respect to clinical observations, Bergman and Escalona(1) described young children who were unusually sensitive to stimulation. These children appeared to react strongly but not necessarily negatively to very mild stimuli. They also reacted negatively to moderate stimuli and showed unusual sensory discriminatory capabilities and preoccupations. They also later developed childhood psychosis. Soviet psychologists(21) also describe extremely sensitive children but state that while some of these children become psychotic others develop into unusually gifted individuals.

However these were all clinical observations; sensory thresholds and discriminatory capacities were not experimentally determined. In approaching the problem of sensory capacity we decided to use a technique which would perhaps be related to some important neurophysiological processes. Ma-

goun(3) and Jasper(4) have emphasized the role of the ascending and descending non-specific reticular activating and inhibiting systems and the non-specific thalamic systems especially as related to arousal and attention. Differences in the functioning of these systems may affect the development of the child. Furthermore certain behavioral phenomena that are related to sensory capacity have been said to be mediated by these rather important neurophysiological systems. Larsson(5) has demonstrated electrophysiologically the relation between reticular arousal mechanisms and the startle response. Bartoshuk(6) has shown the connection of these arousal mechanisms and the phenomena of habituation, adaptation, or cessation of a startle response.

We therefore thought that if we studied the infant's ability to habituate his startle response to a sensory stimulus we would be measuring some aspects of his sensory capacity and also some aspects of the neurophysiological functions of his thalamic and reticular systems. There were 2 main questions confronting us: do new-born infants show the phenomena of habituation and do they have the capacity for sensory discrimination? In respect to the latter, all previous literature state rather unequivocally that babies do not show sensory discrimination in any modality.

The first part of our study then was to determine if babies can habituate or adapt their responses to a stimulus consecutively repeated. By habituation we mean decrement and cessation of response with repeated application of a constant stimulus.

The subjects for this study were 50 normal full-term babies from the new-born nursery at Bronx Municipal Hospital Center, ranging from 1 to 5 days old. They were taken to the adjoining laboratory at a set time between feedings. During the experimental session their heart rate was measured continuously with a direct writing, standard electrocardiograph utilizing 2 precordial leads. Violent activity did not in-

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

This investigation was supported in part by U.S.P.H.S. Mental Health Career Investigator Grant (M-2249).

² Albert Einstein Col. of Med., New York 61.

terfere with heart rate measurements. The experimental procedure consisted of stimulating the infants with a repetitive series of pure tone auditory stimuli which had a constant loudness intensity. The interval between stimuli and the length of the stimulus was varied according to experimental design by means of an electrical timing mechanism and 3 observers made independent notations as to the presence and intensity of the behavioral response. The stimulus was produced by an audio-frequency oscillator with a graded volume control. In order to overcome the role of the state of the baby we used a stimulus intense enough to produce a response no matter whether the baby was deeply asleep or vigorously crying. However, some babies when crying or asleep did not respond to the most intense stimulus and we always had to vary the interval or novelty of the stimulus to determine whether the baby's cessation of responding was due to habituation and not a temporary shift in state of arousal. The same procedure was utilized in studying tactile stimulation. This tactile stimulus consisted of an air-stream directed at the abdomen or arm, whose force was just sufficient to produce an indentation of the skin. The heart rate reached during the first 5 seconds of stimulation was measured. This measurement has been shown by a previous experi-

ment(7) to be relatively independent of the pre-stimulus state. These heart rate measurements did not give us any additional information but confirmed our behavioral observations. When the baby startled, his heart rate went up to his individual startle heart rate level. When no behavioral response was observed the heart rate level remained relatively the same. Our results indicate that many babies have the ability to habituate their arousal response if the stimulus is applied with an interval of less than 5 seconds. This habituation goes through 2 phases. 1. The cessation of the marked startle. 2. The cessation of any response at all. All babies showed the first phase, while only some babies showed the 2nd phase. Among the variables of this habituation process we found that lengthening the duration of the stimulus and shortening the interval between stimuli decreased the number of repetitions necessary for habituation. This is illustrated in Figure 1. There were some babies who did not completely habituate even when the interval was $\frac{1}{2}$ second and the stimulus was repeated over 30 times. In an exploratory manner we found that by using a constant 20 second duration with a 3 second interval, we could distinguish babies one from the other by noting the number of trials necessary for the 2 phases of habituation. Our tentative

The ratings of behavioral responses of an individual baby to a series of constant pure tone auditory stimulations. The ratings are pooled from three independent observers and were as follows: +++ = full startle, ++ = modified startle, + = any behavioral evidence that the baby heard the stimulus, — = no behavioral change with stimulation. The duration is the length of time the stimulus is on, or being applied, and the interval is the length of time between stimulations.

empirical classifications include 4 groups : babies who respond to *most* of the stimuli and either habituate quickly or not at all ; and babies that respond to *few* of the stimuli and either habituate quickly or not at all. We are in the process of testing the day to day constancy of these measurements.

While conducting these habituation studies we conceived the idea of using this technique to determine whether babies can discriminate pitch or auditory frequency. Our method was to habituate the babies' response to a pure tone, and when the baby was no longer giving any responses to this tone, we substituted a different pure tone and noted the behavioral and heart rate response. Since the degree to which loudness depends on frequency decreases as the level of intensity rises, we used an intense tone and also controlled for the loudness contour. In order to get good habituation we extended the duration of the tone to 40 seconds and decreased the interval to $\frac{1}{2}$ second. Figure 2 illustrates our results. Af-

ter the baby showed no behavioral or heart rate response to 3 consecutive applications of tone 400 c/s, in the next $\frac{1}{3}$ second interval we switched to tone 1000 c/s, and the babies usually startled and showed an accompanying increase in heart rate. We then habituated the response to tone 1000 c/s, and switched back to tone 400 c/s, and the babies startled again. We were able to demonstrate pitch discrimination in 15 babies but not in others, and the limits of this discrimination varied. One baby could discriminate between tones of 200 c/s and 250 c/s. Of course if the baby did not habituate we could not test discrimination. We applied this technique to tactile stimulation in a few babies and found that if an air puff is applied for 5 seconds to the right hand with intervals less than 3 seconds the baby habituates his responses, and when it is then applied to the left hand, the response returns and vice versa ; the same holds true for the right and left sides of the abdomen.

It is thus rather evident that human neo-

FIGURE 2
SENSORY DISCRIMINATION

Pitch or auditory frequency discrimination in a two day old infant. The heart rate response is indicated by the level of heart rate reached during the first 5 seconds of stimulation. The behavioral responses shown above the bars, are rated as in Figure 1. The trials indicate the number of consecutive stimulus applications necessary for complete habituation. Three additional trials were given after habituation occurred and before the switch to the novel stimulus.

nates show the phenomena of sensory habituation and sensory discrimination. Perhaps measurements of these phenomena when applied as a technique to distinguish babies one from the other may point up differences in basic sensory capacities and differences in the neural mechanisms subserving general excitation, inhibition and attention processes.

What are implications of the existence of habituation and discrimination in the neonate in regard to neocortical functioning in the neonate? Recent Soviet experiments by Dr. Eugene Sokolov(8) indicate a similar phenomenon in human adults with a crucial difference. He describes habituation to auditory stimuli but also states that when the interval between stimuli is decreased or the intensity of the stimulus is decreased the response occurs again. He ascribes this function to the existence in the neocortex of a neuronal model of the stimulus. Our babies did not lose their habituation to a given stimulus if the stimulus was decreased in intensity or applied after a shorter interval. The response only returned if the interval between stimuli was lengthened, not shortened. Adult habituation is apparently of a different order and the neonate's habituation is not necessarily dependent on the neocortex. Sokolov also describes some experiments with 1-day-old infants in which, with a change in the spatial localization of the source of the sound, the response returns again.

Specifically relevant to our own studies are Sharpless and Jasper's(4) neurophysiological experiments on the habituation of the arousal reaction in cats. They found that there are 2 types of arousal reactions—one very susceptible to habituation, the other more resistant to habituation. The type that is resistant to habituation was said to be related to non-specific thalamic mechanisms subserving attention processes, while the type susceptible to habituation is related to the lower reticular activating system. In our own study we also found 2 types of arousal responses with different rates of habituation. Individual differences in these mechanisms may be important indices of temperamental properties. Sharpless and Jasper also demonstrated that decorticate

cats show habituation and pitch discrimination.

Thus we feel that the pitch discrimination demonstrated in our experiments does not depend on the functioning of neocortical structures. This primitive type of sensory discrimination is of a different order from that shown by mature organisms which is really discrimination by learned differentiation. The usual method of studying sensory discrimination in non-verbal subjects involves the use of conditioned reflex techniques. The subject is conditioned to one stimulus and automatically generalizes the conditioned response to all similar stimuli. Only the original stimulus is reinforced and the other stimuli undergo conditioned inhibition. The subject learns to differentiate the stimulus that is reinforced, from all others, and this discriminatory capacity is determined by the extent of the conditioned inhibition. Since conditioned inhibition is poorly developed in infants(2) they have a low capacity for learned sensory discrimination, even though our habituation experiments demonstrated some sort of primitive sensory discrimination.

Both Hernández-Péon(9) and Galambos(10) performed neurophysiological experiments and concluded that the inhibitory mechanism responsible for sensory habituation is located in the mid-brain reticular system. Precht(11) in his study of the central adaptation of the head turning responses in babies also located the process in the reticular system. This sort of primitive discrimination has been reported for premature babies by Dr. John Benjamin(12).

In respect to the problem of measuring sensory capacity, a few comments may be pertinent. In an earlier study(7) we correlated babies' heart rate responses with their pre-stimulus heart rate and found that babies differed from each other in the slope of the regression lines. We thought that these differences in the functioning of the "law of initial value" may reflect differences in homeostatic efficiency. While this may be true we also feel that these differences may indicate differences in sensory thresholds and capacity. We found that when a weak stimulus is used, the slope of the regression line becomes flatter and the scatter is great.

FIGURE 3

Best fitting regression lines of patterns of heart rate responses produced with stimulation of different modalities in an individual baby.

er—the “law of initial value” is not so valid. Perhaps for a given intensity of stimulation, babies whose heart rate responses are erratic have a higher threshold than babies whose heart rate responses conform rather rigidly to the “law of initial values.” In support of this idea is the observation by Freedman(13) that premature babies don’t conform to the “law of initial values,” and Graham(14) has shown that brain damaged infants have a higher pain threshold than normals.

As to the problem of comparing different sensory modalities Figure 3 illustrates a technique which may be useful. We apply an inhibitory stimulus (warm water) and get a low stimulus heart rate, then cold water and get a high stimulus heart rate, and then apply the test stimulus—tactile or auditory *etc.* and calculate how much of the range was used up with this stimulation. We can thus compare babies in respect to

their differential sensitivities in the various sensory modalities.

SUMMARY

In summary, in the process of exploring the neonates’ behavioral and autonomic repertoire for the purpose of devising techniques that would enable us to measure temperamental differences, we have come across two phenomena that we would like to emphasize. First we described the neonate’s ability to habituate his responses to sensory stimuli and pointed out its possible relations to the neurophysiological structure subserving arousal, inhibition and attention; second we demonstrated that neonates have the capacity for sensory discrimination but noted that this primitive discrimination and habituation need not be dependent on the functioning of cerebral cortex and does not appear to be identical with the same phenomena in the mature organism.

COMBINED DRUG THERAPY OF CHRONIC SCHIZOPHRENICS¹

Controlled Evaluation of Placebo, Dextro-Amphetamine, Imipramine, Isocarboxazid and Trifluoperazine Added to Maintenance Doses of Chlorpromazine

JESSE F. CASEY, M.D.,² LEO E. HOLLISTER, M.D.,³ C. JAMES KLETT, Ph.D.,⁴
JULIAN J. LASKY, Ph.D.,⁴ AND EUGENE M. CAFFEY, JR., M.D.⁵

The proportion of psychotic patients released during their first two years of hospitalization has varied considerably over the past 30 or 40 years, but the release rate of those who have been hospitalized more than two years has remained steady(1). This trend has increased the proportion of chronic schizophrenic patients in mental hospitals, creating an especially important therapeutic problem in Veterans Administration Neuropsychiatric Hospitals, most of whose patients first became ill during or soon after service in the first and second world wars. Treatment of such chronic schizophrenics has been attempted with combinations of sedatives or tranquilizers with stimulants or antidepressants(2-18). Most investigators concluded that combinations increased therapeutic effectiveness although a few, well-controlled studies failed to support this contention(19-21).

Many chronic schizophrenic patients in VA hospitals were known to be on maintenance treatment with phenothiazine derivatives. A large-scale cooperative study was designed to explore the possible enhancement of conventional treatment by the addition of the new antidepressant drugs. Five hundred and twenty patients currently being treated with chlorpromazine (Thorazine) were obtained from 26 hospitals for 20 weeks of combination treatment.⁶ Drugs

added were dextro-amphetamine, imipramine, isocarboxazid, trifluoperazine and placebo.⁷ This report presents the over-all plan of the study, clinical results and major side effects. Other aspects of the study, for example, patient-staff attitudes related to treatment response, and a comprehensive report of side effects and laboratory data will be published separately(22).

PROCEDURE⁸

Each hospital prepared a list of 40 apathetic, withdrawn, but physically healthy schizophrenic men. All patients had been treated with 200-600 mg. of chlorpromazine daily for two or more months without current improvement. Patients with a lobotomy, neurologic disease or seizures, toxic psychosis or prior treatment with the study drugs were excluded from the sample. Twenty eligible patients from each hospital were then randomly selected and assigned to the various drug combinations by the Central NP Research Laboratory at Perry Point, Md. A double-blind procedure was employed in drug administration.

⁵ VA Hospital, Perry Point, Md.

⁶ The following VA-NP hospitals participated in

The sample of 520 patients ranged from 21 to 55 years in age, the mean being 38 years. The average patient had been hospitalized 8½ years during his current stay. This was the first hospitalization for 21%; the second or third for another 57%. Only one patient in 5 had left the hospital for more than a week's planned absence during the year preceding the study. Nearly 78% had never been married; less than 8% were currently married. The average patient had completed 9½ grades of school. Fifty-four per cent had worked only at unskilled jobs and another 17% had never held a steady job.

Symptomatic response to the study drugs was evaluated by two measures: The Inpatient Multidimensional Psychiatric Scale or IMPS(24) and the Psychotic Reaction Profile or PRP(25). In terms of their pre-study measures these patients demonstrated more withdrawal, disorientation, conceptual disorganization and motor disturbance than the average VA patient but less grandiose excitement, agitated depression, paranoid projection, hostile belligerency, perceptual distortion and excitement. Withdrawal includes such behavior as retarded speech and movement, apathy and lack of relationship with others. Disorientation to time or place was present to some degree in about 45% of the sample. Patients with high scores on motor disturbance grin and grimace inappropriately, while conceptual disorganization scores reflect irrelevant, repetitive, rambling or incoherent speech including neologisms. The sample was reasonably typical of a group of withdrawn, chronically ill schizophrenics, not particularly active or disturbed and showing little affect, either in the form of depression or elation.

During the study, each patient remained on his individually established dose of chlorpromazine. Coded medication in identical appearing capsules was supplied to the hospitals in the following strengths: dextroamphetamine, 10 mg.; isocarboxazid and trifluoperazine, 5 mg.; imipramine, 37.5 mg. and placebo. During the first 4 weeks, a predetermined dosage schedule was followed: days 1-3, one capsule; days 4-7, two capsules; days 8-14, three capsules and days 15-28, four capsules. During the final 16 weeks, medication was prescribed within

the limits of 1 to 6 capsules daily. "Activator" medication was not dispensed during the late afternoon. Results indicated that dosage was used through the full range with 60% of all patients being on maximum dosage during the last few weeks of the study.

Pairs of raters independently evaluated all patients immediately before the study and after 4 and 20 weeks of combined drug treatment. Psychiatrists and psychologists interviewed the patients and completed the IMPS; nurses and nursing assistants completed the PRP on the basis of recent ward observations. Data relating to clinically observable side effects, blood pressure and hematologic changes, and hepatic function were obtained at regular intervals.

Fifty-eight patients were not included in the final analysis of data: 27 were dropped for medical reasons and 31 were excluded for administrative reasons, usually incomplete data.

The statistical method for evaluating therapeutic effectiveness of the drug combinations was analysis of multiple covariance (simple randomized design). Each of 17 symptom clusters, 10 from the IMPS and 7 from the PRP, was analyzed for relative change over the first 4 weeks, the following 16 weeks, and for the entire 20 weeks. Final mean scores in each analysis were adjusted for pre-study status on the variable being analyzed as well as for the net effect of 11 prognostic or control variables: age, length of current hospitalization, number of prior hospital admissions, current marital status, anticipated community placement if discharged, number of times on trial visit or leave of absence during the year preceding the study, education, work level, use of alcohol as a contributing factor in the present hospitalization, chlorpromazine dosage and initial body weight. This adjustment served to equate the groups prior to study and to increase the sensitivity of the tests of mean differences. The findings, based on 510 comparisons (10 for each of 17 criteria over 3 time periods) were also subjected to a multiple range test for further protection against chance effects(26). The 5% level of statistical significance was applied throughout.

RESULTS

Clinical Ratings^a

Changes after 4 weeks of combined drug treatment were not impressive. Significant differences between treatments were observed on 4 IMPS measures (paranoid projection, agitated depression, motor disturbance and conceptual disorganization) but on none of the PRP measures. Of these four, only conceptual disorganization was significant by the end of the study.

Symptom reductions indicated by the

^a Detailed statistical tables containing the adjusted means, F ratios, and results of the multiple range test for all criteria at the three evaluation periods may be found as a statistical supplement in the Appendix of the Transactions of the Fifth Annual Research Conference on Chemotherapy in Psychiatry (23). Inquiries concerning additional statistical or procedural details may be directed to the Central NP Research Laboratory, Perry Point, Md.

IMPS after 20 weeks of treatment are summarized in Figure 1. Significant differences between the various drug combinations were noted on 5 of the 10 scale measures. *No combination of drugs was more effective than chlorpromazine with placebo.* The best combination for controlling excitement was trifluoperazine. Trifluoperazine and imipramine combinations were each superior to the other two in reducing disorientation and conceptual disorganization but neither was superior to the other. Withdrawal, one of the target symptoms, was more effectively treated by imipramine and isocarboxid combinations than by added dextro-amphetamine; imipramine combination also surpassed the trifluoperazine combination. The dextro-amphetamine combination aggravated hostile belligerency; all other combinations were superior in reducing this symptom cluster.

FIGURE 1

CHANGES IN SYMPTOMS AFTER 20 WEEKS OF COMBINED DRUG THERAPY
INTERVIEW TEAM RATING (IMPS)

Changes on the PRP after 20 weeks of treatment are presented in Figure 2. Significant differences between treatment groups were noted on 6 of the 7 measures. As on the IMPS, one or more of the added drugs was superior to the dextro-amphetamine combination but none was superior to chlorpromazine-placebo. The IMPS and PRP reflected similar withdrawal and conceptual or thinking disorganization changes. On the PRP, however, agitated depression was affected differently by the various combinations, imipramine and placebo appearing better than the others.

Besides comparing treatment groups with each other, data were analyzed to compare changes *within* each treatment group over the 20-week period. Significant changes in each treatment group are shown in Table 1. Addition of placebo to chlorpromazine produced significant improvement in 8 of 17 criterion measures as contrasted with 9 of

17 improved by adding trifluoperazine. On the other hand, significant worsening on 3 measures followed addition of dextro-amphetamine. Specific drug effects on symptoms were difficult to distinguish, though trifluoperazine appeared to improve further such psychotic symptoms as disorientation, conceptual disorganization, perceptual distortion, and thinking disorganization. Perhaps equivalent augmentation of the dose of chlorpromazine would have done the same.

Two major conclusions may be drawn regarding 20 weeks of combined drug therapies. First, none of the combinations of chlorpromazine and an activating drug was superior to chlorpromazine alone (with placebo). Second, addition of dextro-amphetamine to maintenance therapy with chlorpromazine not only may impair continued improvement but may actually make patients worse. Of the three newer

compounds, adding imipramine or trifluoperazine appeared to be superior to adding isocarboxazid.

SIDE EFFECTS AND LABORATORY FINDINGS

Complications of treatment were infrequent, seldom necessitating removal of patients from the study. Side effects were often observed prior to addition of the test drugs, further decreasing their significance during the study. Twenty-seven patients were terminated early because of medical complications not necessarily related to drug therapy. Five patients were dropped because of intercurrent illness, 3 for gastrointestinal bleeding and 7 because their psychiatric condition worsened. Three of 4 patients dropped for neurological effects were receiving trifluoperazine. Three patients, all getting dextro-amphetamine, were dropped because of weight loss. Hypotension accounted for one dropout, tachycardia for 2 others. One patient receiving trifluoperazine was terminated in the 14th

week because of the development of leukopenia. Another patient was terminated because of distinctly elevated SGO-T titers but his prestudy SGO-T titer was so abnormal that this complication could hardly be ascribed to his study medication. There were no instances of jaundice or agranulocytosis. Dropouts for specific reasons were not differentially related to type of medication although the greatest number over-all were from the dextro-amphetamine group.

No side effects before or during treatment were reported for 255 of the 462 patients. The incidence of specific side effects was also low. The most common one, cardiovascular disturbance, was reported for only 36 patients. Differences among treatment groups were significant for two specific side effects only: of the 17 patients who developed extrapyramidal symptoms during treatment, 9 were in the trifluoperazine group; 10 of the 17 patients reported as demonstrating loss of appetite were receiving dextro-amphetamine. There was no relationship between dosage level of chlorpromazine and the incidence of side effects and abnormal laboratory findings.

Deviant laboratory findings were evenly spread among the treatment groups. At one time or another, 55 patients had eosinophilia (eosinophil count > 6%), 74 had leukocytosis (total leukocyte count > 13,500 cu. ml.) and 17 were leukopenic (total leukocyte count times per cent neutrophils < 1,800). Hepatic tests, predominantly the serum glutamic oxalacetic acid transaminase test, were abnormal for 91 patients (SGO-T > 40 units). However, each of these deviations is inflated as many patients had only isolated abnormalities while others also had them prior to study.

Weight changes over the 5 months of study were sufficient to be considered a complication. By the end of the study all groups showed significant changes in weight. The dextro-amphetamine group lost 4.5 pounds on the average while all the other groups gained weight; 12.5 pounds in the imipramine group, 9.5 pounds for isocarboxazid and approximately 4 pounds for trifluoperazine and chlorpromazine alone. In the case of imipramine and isocarboxazid, weight gains were significantly higher than from adding trifluoperazine or

placebo. In some instances, this side effect was clearly undesirable. The extremes of individual weight changes ranged from a loss of 52 pounds to a gain of 84 pounds.

DISCUSSION

The average patient in this study was a 38-year-old, modestly educated, vocationally unskilled bachelor. His social and economic adjustment prior to hospitalization was poor, being worsened by almost a decade of current hospitalization. During this period, he was refractory to treatment, including drug therapy. Although seriously ill from a social viewpoint, he no longer manifested the flagrant psychotic symptoms that might have been present earlier in his illness. The number of such patients is large enough in all psychiatric hospitals to more than justify the continued search for a means of stimulating further improvement.

In the light of the clinical problem posed, a controlled study seemed indicated. Dramatic improvement was neither expected nor did it occur. After 5 months of treatment, there was a statistically significant reduction in symptom ratings in all but the dextro-amphetamine group. Positive changes, although statistically reliable, were not clinically impressive; no patient improved sufficiently to be discharged or to be granted a trial visit. Current drug therapies, however effective for acutely ill schizophrenics, cannot be expected to change what has become a way of life for these chronic patients or to supply the social, economic and personality resources which they lack.

One reason for the relatively poor result of the drug combinations was the improvement patients made after merely adding placebo to their maintenance chlorpromazine. This might reflect the continuation of a gradual long-term trend toward improvement or the effect of 5 months of additional therapy with chlorpromazine. However, patients were selected because of clinical stability and most had been receiving chlorpromazine for well over two months. Rater bias toward improvement might account for the improvement but this seems unlikely as raters detected the worsening of the dextro-amphetamine group. The most likely speculation is that patients

responded positively to increased staff attention, though such a placebo effect was not observed in two similar studies (27, 28).

Attempts to single out selective drug actions proved futile as the added drugs were no better in reducing symptoms than chlorpromazine alone. Trifluoperazine added to chlorpromazine appeared to enhance antipsychotic effects (reduced disorientation, conceptual disorganization, perceptual distortion, thinking disorganization and excitement) over some other combinations, while imipramine exceeded trifluoperazine in controlling agitated depression, withdrawal and inactivity.

While these particular drug combinations were not especially effective, they were safe. Only 5% of the patients were dropped from the study because of side effects or complications, not all of which were clearly related to treatment. As in earlier VA cooperative drug studies, abnormal symptoms, signs and laboratory tests were usually distributed evenly among the treatment groups (29). Two clear cut exceptions were the increased prevalence of extrapyramidal syndromes following addition of trifluoperazine and loss of appetite from adding dextro-amphetamine. With the exception of dextro-amphetamine all other drug combinations were accompanied by some weight gain.

We should like to emphasize that our findings regarding drug combinations apply only to the manner we used them; that is, by adding activator drugs to maintenance treatment with chlorpromazine. Combined drug therapy has also been used by starting both classes of drugs concurrently or treating first with a stimulant (possible exacerbating the psychosis) and then following with chlorpromazine (19). We rejected these approaches largely on the basis of practicability and possible hazards, but the results of this study do not apply to these alternate methods.

SUMMARY

Five hundred and twenty chronic, withdrawn and apathetic schizophrenic men were selected for 20 weeks of treatment with combined drug therapy. All had been on maintenance doses of chlorpromazine (200-600 mg.) for 2 or more months. Activator drugs were added to chlorpromazine and

libidum in the following maximum daily dosage (or less) : dextro-amphetamine, 60 mg.; isocarboxazid and trifluoperazine, 30 mg.; imipramine, 225 mg.; and placebo.

Prior to the study and after 4 and 20 weeks of treatment, 462 patients were rated on 17 measures from an interview scale (IMPS) and a ward scale (PRP). Changes after 4 weeks of combined drugs were not impressive. At the end of 20 weeks, every treatment group except dextro-amphetamine improved, including the chlorpromazine-placebo group. None of the drug combinations was superior to chlorpromazine and placebo. Adding dextro-amphetamine increased hostile and paranoid belligerency and thinking disturbance.

Only 5% of the patients were dropped from the study because of side effects or complications. Abnormal laboratory tests were also infrequent and evenly distributed among the treatment groups. Trifluoperazine added to chlorpromazine increased the prevalence of extra-pyramidal syndromes, while dextro-amphetamine produced appetite and weight loss. All other treatment groups gained weight, significantly more from adding imipramine and isocarboxazid than from adding trifluoperazine or placebo.

Although the present study did not demonstrate substantial benefit from combined drug therapy, the chronicity of the patients and the method of drug administration limit generalization.

BEHAVIORAL CHANGES IN PATIENTS WITH STROKES^{1, 2}

MONTAGUE ULLMAN, M.D., AND ARNO GRUEN, Ph.D.³

Two broad points of view embodied in the work of Kurt Goldstein(1) and the more recent studies of Weinstein and Kahn (2) have evolved concerning the nature and origin of behavioral disturbances in brain-damaged patients. Although in many ways the views on denial expressed by Weinstein and his associates are an outgrowth of the earlier work, there are also certain significant differences.

Goldstein emphasizes the incapacity of these patients to function at an abstract level. He describes a particular deficit, namely, the inability to make choices or to deal in the realm of the possible. His interpretation of a great many of the manifestations of these patients is in line with the concept that they seek to limit their environmental contact to areas of adequate stimulation. He speaks of avoidance as a biologically induced process designed to minimize or to eliminate the occurrence of a catastrophic reaction.

The emphasis of Weinstein and Kahn appears to be more on the motivated aspect of the patient's responses, as these are manifested in the patient's effort to express himself and his values through altered patterns of symbolic organization. The experiential content becomes meaningful when viewed through the social and cultural screen of the patient's idiosyncratic life experiences. The response is then a function of whatever the characteristic defensive style of the patient may be, with the level of alteration in the brain milieu influencing the manner in which this style is symbolically expressed.

We have had the opportunity in the course of a 3-year period (1957-1960) to

make a number of observations on patients admitted to a general hospital during the acute phase of a cerebro-vascular accident. It is our purpose to present some of our findings and to discuss them in the light of the above-mentioned points of view.

A total of 390 patients have been seen to date. We have selected for consideration 84 patients. This group represents those who experienced a hemiparesis or hemiplegia and where adequate psychiatric data were available. Eliminated from this report are 48 patients with severe aphasic disturbances, 74 who had strokes but no motor deficit, 94 who died soon after admission either of the effects of the stroke or complicating illness, and 90 where the data were inadequate because of language barriers or limited hospital stay.

The 84 patients were classified according to whether the psychological deficit on clinical estimate appeared to be mild, moderate or severe. Patients were rated as mild who showed no gross impairment in the interview situation when questioned about their illness and past history. Those rated as severe showed global defects in general orientation and responsiveness. Those rated as moderate represented an intermediate group with uneven performance and fluctuating levels of response.

FINDINGS

The age distribution, neurologic and electroencephalographic findings, and the disposition of the patients in each of these categories are given in Tables 1, 2, and 3 respectively.

Age: Distribution of age appears similar for the moderate and severe groups (Moderate: average 66.8 years, range 50 to 80; Severe: average 65.1 years, range 40 to 81). Though the distribution of age categories of the mild groups overlaps with those of the moderate and severe groups, 13% of its population comes from the 30-39 year age bracket. Since the latter contributes nothing to the moderate and severe groups, it alone accounts for the lowered

TABLE 3
Disposition of Patients in All Groups (84)

GROUP	MILD	MODERATE	SEVERE	TOTAL
Home	35	7	3	45
Care of Relatives	9	1	0	10
Nursing Homes	7	8	1	16
Psychiatric Hospital	0	1	4	5
Died	1	4	3	8
TOTALS	52	21	11	84

average age of the mild group (average : 58 years, range 33 to 82).

Neurologic and Electroencephalographic Findings : As compared with the moderate and severe groups, the motor loss in the mild group tended to be less severe, as did the sensory changes and the EEG findings. There were also fewer associated field defects. The moderate and severe groups cannot be reliably differentiated for comparative degree of brain damage on the basis of these variables.

Disposition : Although many factors other than level of brain damage enter into the disposition, the latter undoubtedly plays an important part. The groupings can be most clearly differentiated on the basis of this factor. Of the 52 patients in the mild group, 35 went home, 9 were cared for by relatives, 7 went to nursing homes, and 1 died while in hospital. This death was attributable to myocardial infarction several months after admission. The trend in the moderate and severe groups was toward higher incidence of nursing home care, psychiatric hospitalization, and death. The deaths in the moderate and severe groups were directly related to the stroke. Psychiatric hospitalization in each instance was on the basis of organic dementia.

MILD DEFICIT GROUP (52 PATIENTS)

In these patients the stroke was experienced without any striking alteration in the general level of consciousness. In connection with the onset of a stroke there appears to be no direct awareness of any cerebral disturbance *per se*. Awareness of illness occurs as an indirect effect following upon the actual experience of sensory and motor dysfunction.

These patients were specifically questioned concerning their subjective experiences during the initial stages of the illness. Two general categories of response were noted :

In 30 patients there was immediate awareness of disordered function and rapidly thereafter insight into the nature of the illness and its possible implications.

Example 1 : When I got dressed I knew something was funny—I could not get my hand in my sleeve. As I got out of the cab I

fell and acted as though drunk. I noticed my speech was wrong. I knew I had a stroke. I was frightened.

In the remaining 22 patients awareness gradually occurred through repeated perceptual experience relating to manifest motor difficulty or on the basis of the patient's observations of the reactions of others to him. Eventual integration of the experience occurred.

Example 2 : I woke up in the morning—I tried to get out of bed. All of a sudden I was half paralyzed. I managed to walk downstairs. I wanted to cross the street and get something to eat. I could not think of anything. I thought perhaps it was a cold settling on my spine. When I talked to people they looked at me in astonishment. There was something wrong with my speech.

Example 3 : I was home—in the toilet—I came out and I fell—could not get up. I used my strength and went to bed. I walked (about 20 blocks) to the hospital. I know I was weak—could not stand up good—I heard about strokes—but did not believe I had one.

In the mild deficit group taken as a whole, the reaction to the illness occurs in terms of characteristic personality patterns and without obvious alterations stemming from the brain damage *per se*. In the examples given, idiosyncratic attitudes toward serious illness, physical handicap and possible death can be noted. These include feelings of helplessness and anxiety (Example 1), minimizing the event (Example 2), and denial (Example 3). Only 2 severe reactive states were noted in this group, both in the form of depression.

MODERATE DEFICIT GROUP (21 PATIENTS)

These patients showed an unevenness of performance during interview. A characteristic feature was various denial patterns in an interpersonal context in matters pertaining to the illness. Along with this was the relatively intact capacity to provide appropriate responses in other unrelated or more remotely related aspects of the patient's life.

Example 4 : Patient is a 58-year-old Negro female with a left hemiplegia. The onset of the stroke occurred at night. The patient awoke and was aware of feeling a strange and un-

attached arm lying in bed next to her. Her first thought was that it belonged to her dead husband.

When first seen in the hospital she was disoriented for time but not for place or person. She exhibited explicit verbal denial of disability. The following is a verbatim abstract from an early interview:

Q. Do you feel anything wrong? A. No, only a headache.

Q. Which is your left hand? A. This. (Makes no sign as to what she is referring to.)

Q. Show it to me. A. Here it is. (Reaches over to left hand with right hand without looking toward left side and with difficulty extracts arm from under bedclothes.)

Q. Is it O.K.? A. Yes, it feels O.K.

Q. Any weakness? A. No.

Q. Move your hand. A. Away up in the air?

Q. Yes. (Patient makes no attempt to move her hand.)

Q. Why don't you move it? (No reply.)

Q. Can you move it? A. Yes. (Still makes no move.)

Q. I don't believe you can move it. A. Yes, I can. (Heatedly, but makes no move whatever.)

Q. Well, go on—move your hand. A. I'll do it right now. I'll put my hand on my head. (No move.)

Relevant and appropriate responses were elicited when questioned about matters in her own past.

The patient presented a relatively uncomplicated and realistic personality structure. The Rorschach findings confirm the impression of stable and strong personal attachments and a strong sense of fulfillment and gratification in her role as a mother. She appears to have accepted her lot and to be mainly concerned with meeting the realistic problems of living.

The functional deficits noted in this patient included anosognosia, disordered sensation on the impaired side, and personification of the left upper limb. Her initial subjective reactions resulted in the notion that this strange detached arm lying in bed next to her was that of her dead husband. She was sufficiently convinced of this to fear having the lights turned on, but did not persist in her fantasy once the lights were turned on. The relief of anxiety in this instance was associated with disproving this feeling about her arm. The initial identification did not occur on the basis of wish-

fulfillment. It simply appeared to be a felt impression arising out of her own past experience of lying in close proximity to a bodily appendage that was not part of her own body, namely, the arm of her husband. The personification represented an integration at a concrete level of the current perceptual alterations with related aspects of her past experience. The illusory feeling that did persist was a true anosognosia—an unawareness that she was unable to move the arm, and, conversely, a belief that she could do so. The feeling of the patient in the course of these trials resulted in a false belief that she had very little capacity to correct. Questioning in areas unrelated to the illness elicited appropriate responses.

The type of performance described above is characteristic of the moderate deficit group as a whole. There is a clear awareness of the interpersonal situation as such. There is an awareness of the examiner as existing external to and independent of the patient. The appropriateness of response varies with the subject under discussion. When areas of illness and defect are impinged upon, there is a sharp drop to a concrete, stereotyped level of response.

SEVERE DEFICIT GROUP (11 PATIENTS)

In these patients the deficit was of a generalized nature, with gross defects in orientation, memory, confabulation and limited attention span. They tended to appear indifferent or apathetic to their surroundings and did not initiate conversation in the interview situation.

Example 5: Patient, a 55-year-old white male with a left hemiplegia, was disoriented for time and place. He confabulated freely and misidentified those about him. The following is from an early interview:

Q. What is wrong with you? A. I got a cold, sore throat. I haven't seen you for a long time. (The patient then muttered some reference to household expenses.) How are you making out with that place of yours up the street—that rooming house of yours?

Q. Who am I? A. You're the manager here of the hotel, aren't you?

Q. Can you move your arm and leg? A. Sure, enough to handle tools. (The patient was unable to move his arm on the paralyzed side.) Slowly they are coming out of it—it takes

practice. I haven't seen your wife since you—since I'm back.

Q. What is the name of this place? A. Continental Hotel.

Q. What is the date? A. Twelfth of November, Armistice Day, 859. (Actually September 12, 1958.)

When questioning was directed to his past life he confabulated freely and tended to misidentify the examiner as a participant in these past events. He appeared to respond to the visual and auditory cues of the interpersonal situation as if he were reliving past events, or, as if the interview simply served as a prop around which to objectify and externalize his own inner experience. Internal referents dominated responses both in regard to the current illness and his own past.

In this group the deficit was of such a generalized nature that there was little or no appreciation of the interpersonal situation as such, that is, as a new experience containing elements external to the patients themselves. These patients appeared to be experiencing a waking form of dream consciousness in which all stimuli from the outside are either not attended to or evaded; or, if attended to, are reacted to as if they arose from internal sources and had internal referents alone. When specific responses pertaining to the afflicted part can be elicited, as when a patient responds that his arm was removed by a saw, they appear to be the result of thought processes which are inductive and based on analogy. One aspect of an external situation usurps the field and by induction leads to a generalization which is externally and objectively false, but internally consistent with what the patient is experiencing at the time. In the example just cited there is a sense of unconnectedness with the paralyzed arm which is interpreted at a concrete and mechanical level as the arm being physically separated from the body by a saw.

DISCUSSION

In the brain-damaged patient with moderate or severe deficit, the setting in which motivational factors have to be evaluated is qualitatively different from what it is in the mild group. There is a flexibility of form in the latter, with appropriate shifts from

abstract to concrete attitudes guided by the needs arising in a given situation. With progressive functional cerebral impairment the role of personality factors recedes as a determinant of behavior, and the residual capacities shape the response in greater and greater measure. This shift is best characterized in terms of Goldstein's concept of loss of abstract attitude. In patients in the severe deficit group this shift was global and enduring; in the moderate deficit group there were fluctuating levels of performance relative to the demands of the interpersonal situation.

Confusion arises in connection with the use of the term "denial." In ordinary psychiatric usage, it refers to a specific psychodynamic mechanism designed to so influence the demands of the interpersonal situation in which the patient finds himself as to enable him to function without anxiety by selectively pushing out of awareness a painful or disturbing aspect of his own existence. Denial is a mechanism arising out of an interpersonal context in the first place and designed to operate in that context. Much of what is interpreted as denial in the brain-damaged patient is such only when judged by the standards of normal waking behavior. When judged from the point of view of the patient and the level at which he can relate to the environment, the concept of biological avoidance appears to be a more felicitous designation, as it places the emphasis not on a need to deny, but on the reorganization of the self in relation to the stimuli impinging on it. Central to this whole discussion is the phenomenon of anosognosia(3). To think of this in denial terms implies an awareness by the patient of the deficit or defect and the denial of it to avoid anxiety. Admittedly this occurs in many patients in a later or recovery phase of the illness. The clinical impression one so often encounters in the initial phases, however, with these patients, is that the affected part drops out of awareness and in the reorganization that follows a kind of congealing process takes place based on the remembrance of the part. He appears to deny the existence of the limb or its dysfunction, but what he is actually doing is restricting his perceptual experience in line with what he now believes is his real situa-

tion. The factors operating to limit his awareness exist apart from the interpersonal context. He is not using denial as a psychodynamic mechanism, but as a convenient way of explaining certain felt reactions. The patient is encountering difficulty in relating to the deficit because of his incapacity to adopt the abstract attitude. It is only by means of the latter that he could link the defect to the rest of his existence in time and space. Instead, he deals with it at a concrete level by so ordering the external environment as to avoid reference verbally or in practice to the defect. The crucial question concerns the capacity of the patient to be aware of the defect and not an awareness that is suppressed in the service of avoiding anxiety. What emerges as apparent denial is the effort to cover up the areas of unawareness as these are encroached upon by the environment. The anxiety level becomes a function of the relative success the patient has in covering up or avoiding involvement in the deficit.

SUMMARY

The individual who has had a stroke is reacting to a situation of stress that has many unique features. Patients who have

experienced mild strokes with little or no residual mental impairment react to the stress in their own idiosyncratic fashion. Some will intergrate the experience successfully; others will become enmeshed in psychopathological manoeuvres of varying severity. In patients with moderate or severe brain damage, the situation is quite different. Here the unique features of the stroke are highlighted, the chief of these being that the very organ governing the adaptation to stress is itself impaired. The resulting clinical picture has to be evaluated now, not only in terms of what the experience means to the patient, but also in terms of the capacity the patient has for evaluating the situation.

ROLE: A CONCEPT LINKING SOCIETY AND PERSONALITY

WILLIAM F. KNOFF, M.D.¹

Whereas biological, primarily somatic concepts (*i.e.*, humors, libido, instincts) have served medicine and medical psychology traditionally from Hippocrates to Freud, psychiatry today is increasingly confronted with concepts of a different order, derived by social scientists in the systematic study of social life, which present new perspectives for understanding human motivations and behavior. Inasmuch as attention to the work of fellow scientists is likely to contribute to progress in related fields of scientific endeavor, the discussion which follows is offered to a psychiatric audience.

The purpose of this review is to consider the development of a central, and perhaps integrative, concept in social and psychological science which has attracted steadily increasing attention in recent years: the concept of role. We shall begin theoretically and then proceed to some—by no means complete—implications and applications of role theory. In the theoretical part it may not be possible to avoid level-jumping (attempts to “physiologize” psychology or “sociologize” physiology). But, in the present state of our knowledge, this is hardly a serious crime simply because boundaries have not been sharply drawn and there is as yet no strict definition of the phenomena delimited by the fields of psychology, sociology, anthropology and psychiatry. It would appear that social scientists and psychiatrists look at the same data, but through different lenses.

STATUS AND ROLE

Ralph Linton introduced and defined the inter-related concepts of status and role in his anthropological text, *The Study of Man*, in 1936(6). Although social structure concepts have been employed by social scientists for a hundred years and have been used analytically by them for the past 25 years, psychiatrists have become aware of their usefulness only recently(5, 9). The

concepts of status and role, as Linton originally defined them, are relatively pure concepts delimited within a sociological frame of reference but, by virtue of their gradually increasing application, status and role have acquired a multiple relevance—a process not unlike cultural diffusion—in sociology, social psychology, and, more recently, in psychiatry. The concept of role has proved to be an increasingly useful and enlightening concept. Perhaps it may be shown to be a point or articulation between the areas delimited as the sociological (or what goes on outside a person) and the psychological (or what goes on inside a person) theoretical levels of analysis.

In a discussion of science and concepts, a simple definition of the term “concept” is offered by Chinoy who states “. . . a concept is a general term that refers to all members of a particular class of objects, events, persons, relationships, ideas—of any kind of unit or entity”(3). A concept, therefore, serves an organizing function, and science may be defined as the study of the relationships between phenomena or the concepts by means of which phenomena are expressed.

The status concept is fundamental to a conceptual grasp of role. Actually, status and role are inseparable and can be taken apart only for purposes of definition. In this connection, Parson's hyphenated term “status-role” is expressive(10). The functioning of society depends upon the presence of patterns for reciprocal behavior between individuals or groups of individuals. Patterns for reciprocal behavior are socially institutionalized (formalized) as status-role. Linton defined status as a position in a particular pattern which is “. . . distinct from the individual who may occupy it . . . (and) a collection of rights and duties”(6a). In this sense, status can include the “sum total of all the statuses”(6b) which an individual occupies. (This generalization to status has recently been particularized by Merton(8) who employs the term *status set* to refer to the multiple statuses an individual oc-

¹ Associate Professor of Psychiatry, State University, of New York Upstate Medical Center, Syracuse 10, N. Y.

cupies and the term *status sequence* for the chronological and developmental statuses which a person occupies through the life cycle.) "Thus," wrote Linton, "the status of Mr. Jones as a member of his community derives from the combination of all the statuses which he holds as a citizen, as an attorney, as a Mason, as a Methodist, as Mrs. Jones' husband, and so on" (6c). Having defined status, then, we can now view role as *status in action*. In Linton's words, "A role represents the dynamic aspect of status" (6d). Thus, what Mr. Jones *does* as a citizen, as an attorney, a Mason, a Methodist, as Mrs. Jones' husband, *etc.*, carries status into action and constitutes *role*. Thus, status and role function to reduce cultural patterns to individual expression.

Status and role, or status-role, can be socially *ascribed* or *achieved*. As Linton states, "The individual is socially assigned to a status and occupies it with relation to other statuses. When he puts the rights and duties which constitute the status into effect, he is performing a role" (6e). Obviously, a person *occupies* a status with its corresponding set of rights and duties, while he *performs* a role which is, then, normative behavior.

Status-role provides a means by which society socializes and "educates"—or organizes—its members. Roles become models by means of which the attitudes and behavior of an individual are made congruous with those of other individuals participating in the cultural pattern. Members of a society are recruited into roles via socialization processes which begin at birth, or soon thereafter, and continue throughout the life cycle in a manner reminiscent of Jacques' speech in *As You Like It* which begins: "All the world's a stage, and all the men and women merely players . . ."

REFERENCE POINTS

All societies use certain reference points for the ascription of status. Linton pointed out that such reference points are ascertainable at birth and he listed *sex, age, family relationships* (such as that of child to mother, uncle to nephew, *etc.*) and birth into *class* or *caste* as the important ones (6f). "In all societies the actual ascription of statuses to the individual is controlled by

a series of these reference points which together serves to delimit the field of his future participation in the life of the group" (6g). Action, therefore, and personality development (learning how to act) occur, to a large extent, within the confines of ascribed status and role. They differ widely from culture to culture and change with the times in any particular culture. The delicate, fainting lady of the late 19th century, as a cultural type, is as extinct as the dodo (6h). Approaching extinction also are the "classical" symptom neuroses, *grande hystérie*, and other forms of hysteria studied by physicians from Hippocrates to Freud and upon which Charcot, Breuer and Freud developed basic concepts of modern psychiatry. Expressions of the sick-role change with culture changes, even in the short space of two generations. (The relation of character change to culture change and the impact on psychiatric practice is discussed in detail by Allen Wheelis in his recent book) (13).

"Room to move around" is provided in most societies by the device of *achieved* status. Although most of the statuses in all social systems are ascribed, status can also be *achieved*. The day-to-day living of people in a society is largely handled by means of ascribed statuses which take no account of individual differences, qualities, abilities. As Linton says, "Most of the business of living can be conducted on a basis of habit, with little need for intelligence and none for special gifts" (6i). However, a person may employ his special qualities in a competitive effort to acquire *achieved* status which is left open in a society and is not assigned at birth. Although one's status-role in a particular family in a particular society may be largely *ascribed* by means of reference points of age, sex, class, and family relationships, other status-roles which a person occupies can be *achieved*, especially in other societal sub-groups, such as the work-group or the community, utilizing different reference points. For example, a 22-year-old male may be Mrs. Jones' son in a middle-class American family, but he may also be captain of the football team, or a junior executive, and husband and father in a community quite different in social class from the original Joneses.

ROLE BEHAVIOR

Status is a social structure concept inseparably related to cultural reference points of age, sex, class, or caste, sub-group membership (*i.e.*, family) *etc.* But status—the “collection of rights and duties” (rules of the game)—which may be occupied by a person can only find *expression* through the medium of personal, or so-called “individual” action. Status carried into action (role) constitutes observable and describable behavior. Role behavior can be studied and defined by means of controlled observation. Argyle(2), observes :

There may be said to be a *role* in the social structure sense when the behavior of occupants of a position . . . is modally distributed for a situation, or a class of situations or for each of several classes of situations, and if the mode differs significantly from those of adjacent positions. If the actual behavior of an individual is sufficiently similar to the modal behavior—say within one S.D.—it may be said to be *role-behavior*; this is a psychological concept, whereas role is a sociological one.

Twenty-five years ago, Allport(1) in deriving the J-curve hypothesis of conforming behavior, studied the distribution of behaviors in various situations : motorists stopping (or failing to stop) at traffic signals, time of arrival at work of factory employees, and the behavior of Catholic parishioners in stopping—or not stopping—to dip their fingers in holy water and make the sign of the cross. He concluded :

From the data so far obtained, it therefore appears that when we plot the distribution of behaviors in a situation where individuals are said generally to conform, we find the following condition : Rarely, if ever, do we find that all the individuals conform completely. A varying number conform only in partial degree. The proportions of these are distributed in a diminishing fashion as we proceed to the wider variations in the modal act. Their degree of diminution, moreover, becomes less as we proceed out toward the deviating extreme (1a).

Rather than the usual bell-shaped, normal probability distribution, Allport's data yielded a skewed curve which he called a “double J” or a curve with a single mode.

His work has been followed by a number of other studies employing controlled methods of observation to describe and discover standard modal behavior and the frequencies of behaviors deviating therefrom. Allport's data and that of others (for example, Dudycha's study(4) of the punctuality of college students in a variety of situations) show that most people do what they are taught to do (*i.e.*, punch the factory time-clock at 7 a.m., get to class on time), that is, their behavior would fall under the narrow peak in the “double-J” curve, whereas the partial conformers (called deviants or innovators according to one's point of view) are distributed in diminishing numbers outward toward the extremes from the modal act. The “double-J” curve of conforming behavior seems to typify the distribution of behavioral phenomena which involve learning. On the other hand, if we were to take the same subjects (factory workers, drivers, parishioners, college students) and measure certain unlearned, biological, characteristics such as height, length of bones, *etc.*, we would derive a bell-shaped, normal probability curve. Evolutionary biologists, following Darwin, have observed that variation is one of nature's strong points, perhaps even accounting for the survival of living forms in the struggle for existence. It might be said that social organization, borrowing no wisdom from biology in this regard, limits behavioral variation through conformity control and tends to press behavior into a narrow, modal, range.

SOCIETY AND PERSONALITY

The foregoing sections appear to make sense in a sociological frame of reference. And yet the term “psychological” has been used a number of times as if sociological and psychological frames of reference could overlap, superimpose, or in some other way, blend without loss of conceptual clarity. Such unification, of course, presents many unsolved theoretical problems. But perhaps an approach to integration can be made through the role concept. In the preceding section we tried to answer the question : Through the concept of role can we link so-called individual behavior, studied psychologically, with positional and situational

factors, studied sociologically? We now turn our attention to the question: Can the concept of role provide a point of articulation between the psychological and the sociological theoretical levels of analysis?

In defining the "three aspects of the structuring of a completely concrete system of social action" consisting of the *personality system*, the *social system*, and the *cultural system*, Parsons (10a) points out that, although inter-dependent and interpenetrating, one or the other system is not reducible to terms of one or a combination of the other two. He refers here to the "action" frame of reference. Parsons' concept of action cuts across, and is common to, all three systems (personality, social, and cultural) permitting certain transformations or translations between them but not providing a unified, or single system, theory of behavior—although he does not rule out the possibility of such unification on "some other theoretical level." The role concept also enables us to make translations between events in the sociological and in the psychological systems.

It appears feasible, with present knowledge, to view *role* (an element of organization in the social system) as significantly related to *ego* (an element of organization in the personality system). Relations between these concepts were, of course, anticipated by G. H. Mead in his concept of role-taking (7) and have been developed by other social scientists, psychologists, and, quite recently, psychiatrists (5). The psychoanalytic theory of object relations may prove useful in developing our understanding of the relations between ego, as a unit of the psychological system, and status-role, as a unit of the social system. The system of social relationships in which a person is involved is not only of situational significance but through "internalization" (or, better, *learning*) becomes constitutive of the personality itself. For example, it is generally agreed that the superego represents the internal reflection of moral commandments which are a part of the surrounding culture. It seems logical to assume that roles available in a culture are, similarly internalized (or learned), becoming part of the ego: the sense of "I," or "who I am and how I act." Such considerations militate

against explanations of individual behavior which rest solely upon organismic or mentalistic concepts and fail to take into account related social concepts which focus the organized social situation with which the "organism" interacts. We note today that, as this situational impingement upon personal behavior is increasingly comprehended, the inclusive explanatory power of 19th century physiological (*i.e.*, neuronal) and early 20th century psychological (*i.e.*, id-ego) concepts decreases. Is it more pertinent, we may ask, to study a behaving person as a hierarchy of reflexes, a repository of repressed impulses, or as an experiencing, transacting, learning *being* in a cultural situation? The latter model moves away from cross-section toward a longitudinal perspective of personality as a process of *being* in transaction with objects in socio-historical time: physical objects, social objects, and cultural objects (chairs, people, roles, beliefs, value patterns). Acting human beings are caught up in a world of defined behavior patterns with their corresponding normative orientation—a social world which not only affects but is affected by the people who participate variably in its patterns of living.

SOME IMPLICATIONS AND APPLICATIONS

No attempt can be made here to assess the impact of sociological thinking upon psychology and psychiatry in recent years, nor can we cite inclusively the work which has been done even in what might appear to be the relatively circumscribed area of role. However, we may single out for brief attention certain aspects of

1. Talcott Parsons' concept of the "sick" role in our society and some of the findings in regard to the psychiatric sick-role reported by Hollingshead and Redlich in their recent book, *Social Class and Mental Illness*, (5) and

2. T. Sarbin's concept of hypnotic role-taking.

Parsons formulates 4 institutionalized norms which characterize the roles of sick persons in our society:

1. First, is the exemption from normal social role responsibility . . .
2. The second closely related aspect is the

institutionalized definition that the sick person cannot be expected by "pulling himself together" to get well by an act of decision or will.

3. The third element is the definition of the state of being ill as itself undesirable with its obligation to want to "get well."

4. Finally, the fourth closely related element is the obligation . . . to seek *technically competent* help, namely . . . that of a physician and to *cooperate* with him in the process of trying to get well (10b).

Even a superficial glance at these norms gives one the impression that they are more appropriate to organic illness than to the functional disorders which comprise the bulk of psychiatry. Hollingshead and Redlich, in their research in the New Haven community, studied their application to psychiatric disorders and found: "... first, that most persons with neuroses are not exempted from normal social obligations. . . . Psychotics in all classes, however, are exempted from social obligations . . ." (5a). From this it would appear that the duties of one's role, in our society, cannot usually be abrogated for nervousness but *can* be abrogated for craziness. If this is true, there is no reason to doubt that both nervous people and "crazy" people in our society have learned this "rule of the game." It is quite possible, in fact, to view a psychosis as a most effective way of abrogating intolerable role expectations imposed upon a learning child by a psychotic, or potentially psychotic, parent.

Hollingshead and Redlich observe that most persons with neuroses are not released from normal social obligations; obviously, however, as they imply, some so-called neurotic people are. The social situation, and the individual's perception of it, both make a difference. For example, a patient may obtain prolonged hospitalization (in a general or psychiatric hospital) for the treatment of a psychoneurosis with corresponding exemption from social role responsibilities. However, an attending physician, or other professional employee on the staff of the same hospital, although he may be suffering from symptoms clinically similar to the patient's, will be expected to perform the daily duties of the work role. The patient permits himself to be socially de-

fined as a *patient*—by applying for help—with corresponding exemption from social responsibilities, whereas the professional employee, taking the role of a helping person, avoids being defined as one who needs help. Moreover, the implication here is that one takes the sick role at one's peril. This is the case because, in spite of the fact that in the sick role a person is not held responsible for helplessness, psychiatric help-seeking has negative connotations in our society nevertheless and may even affect other people's perceptions of one's achieved status. This is not the place, however, to discuss the connection between neurotic symptoms and the avoidance of felt obligations. Suffice it to say that exemption from social responsibility is the core of the sick role² and psychiatric help-seeking is not without its price.

3. Role-perception has been defined as the conscious recognition of the kind of behavior which will be approved in a certain role. According to Argyle, (2a)

When role perception is a major factor in behavior, the behavior is often called *role playing*. This covers all cases of acting, imitating, deliberately conforming, and in general creating the impression of being the occupant of a certain position, or creating certain perceptions in the audience.

T. Sarbin, whose research in hypnosis bears upon role theory, sees a close similarity between hypnotic behavior, which he defines as hypnotic role-taking, and the on-stage behavior of the dramatic actor (11). He has developed a socio-psychological concept of hypnotic behavior, concluding that the automatic behavior of the hypnotic subject is a form of role-taking which is congruent with the subject's self-concept; that is, the subject, like a dramatic actor, *wants* to perform the role of the hypnotized subject as he perceives it.

If the subject has an adequate perception of the role, if this perception is not incongruent

² Actually, chronic utilization of the sick-role (chronic functional illness, exaggeration of minimal organicity, "compensation neurosis" etc.) serves an exemption, broader than that defined by our technical concepts, namely, exemption from self-responsible action and its correlates of initiative and integrity.

with his self-perceptions, and if he has an appropriate amount of the role-taking aptitude, then he will produce all the dramatic phenomena of hypnosis merely because "the operator talks to him" (11a).⁸

Sarbin defines the congruence of role and self-concept as favorable motivation for the hypnotic and dramatic situations, pointing out that both dramatic and hypnotic roles are dependent upon it. "The chief difference," he observed, "in the two forms of role-taking was the degree of participation of the self in the role (levels of consciousness)" (11b). The stage actor is more fully conscious of his role than the hypnotized subject although some actors "lose themselves" in their parts more than others do. Where role perception is a major factor in behavior (as in hypnosis, acting, children's play, and perhaps hysterical and other behaviors sometimes colloquially referred to as "phony,") we are dealing with "as if" behavior in Sarbin's formulation. "As if" behavior is characterized by a high imaginative component. As such, it may appear to possess a certain "external" reality creating the approved impression in an audience, but emotional investment and depth are lacking, indeed, conflictual. That is to say, these roles are performed, or played with more or less emotional disengagement.

SUMMARY

The concept of role is considered to be a focal concept derived in the scientific study of social life to which social scientists and

⁸ If we apply here the activity-passivity model of the hypnotic situation described by Szasz and Hollender (12), the hypnotic subject, who perceives his role to be characterized by powerlessness, wants to have something done to or for him by a role-taker to whom he attributes power.

psychiatrists are increasingly turning their attention. A brief review of the development of this concept has been presented and attention called to its possible integrative function in the study of sociological and psychological phenomena. Some implications and applications of role theory are briefly discussed.

THE OBSESSIONAL PERSONALITY AND OBSESSIONAL ILLNESS

I. M. INGRAM, M.D., D.P.M.¹

The obsessional personality was originally a description of premorbid personality characteristics in obsessional patients. The description was widely accepted and came to be applied to a wide range of people; it is now used to describe a type of personality whose possessors are said to be subject not only to obsessional illness but to depressive and anxiety states. With this widening of its scope has come a looseness in its usage. The term "obsessional" is used to describe both symptoms and personality traits, and often a person will be labelled obsessional on the strength of a single characteristic so that, to take an example, to be punctual is to be obsessional.

Despite its extensive use and misuse the description, even in its restricted use, has not been without critics. Freud(2) formulated his own anal-erotic character to describe the premorbid personality of obsessional patients and Lewis(7) noted other characteristics. A descriptive study of a series of obsessional neurotics provided the opportunity to re-examine these different points of view in their original context and assess their validity.

The three different descriptions of the premorbid personality in use must be examined in more detail. They are the conventional obsessional personality, the anal-erotic character of psychoanalysis and the typology introduced by Lewis.

The existence of the "obsessional personality" is widely accepted in English speaking psychiatry and is the most used of these descriptions. At the beginning of this century Kraepelin(6) wrote of the pedantry and concern over trivialities in the premorbid personality of obsessional patients, and Janet(4) described the accepted picture at length. The traits usually included in the description are: "excessive cleanliness, orderliness, pedantry, conscientiousness, uncertainty, inconclusive ways of thinking and acting; perhaps, also a fondness for

collecting things, including money; sexual disturbances, though not of any characteristic sort, are common." (Lewis, 8).

A rough-and-ready, practical description of this kind is open to criticism on the grounds of imprecise definition of its component traits and lack of proof of their co-existence. Lewis(7) noted that the traits could be restricted to one field and absent in another: a person might be over-orderly but not scrupulously clean and not a collector. He did not consider the evidence for the obsessional personality complete and substituted his own typology. Nevertheless, 7 out of 8 British and American textbooks describe an obsessional personality in terms similar to those above.

The anal-erotic character was first described by Freud(2) in 1908 as a "triad of characteristics which are almost always to be found together—orderliness, parsimoniousness and obstinacy." This personality profile differs in its aetiological assumption that the character arises from the dissipation of anal-eroticism. In its descriptive aspects it differs little. Usage of the term has been analysed and contrasted with current usage of the term "obsessional personality" in a previous paper(3). The content was found to differ only in emphasis. For descriptive purposes there is no point in distinguishing them. Here the term "obsessional personality" is preferred, being purely descriptive and without aetiological assumptions, but the results could apply equally to the anal-erotic character.

The third description was given by Lewis and arose from his dissatisfaction with existing ones. In chronic severe obsessional patients he observed two types of personality—one "obstinate, morose, irritable," the other "vacillating, uncertain of himself, submissive." His typology applies to personality in a restricted group of patients and has not been extended and generalised as has the obsessional personality.

For the present purposes then, only two descriptions need be considered—the conventional one and that of Lewis. What

¹ Lecturer in Psychological Medicine, University of Glasgow; Southern General Hospital, Glasgow, S.W.1.

information is already available about their quantitative relation to obsessional illness?

Correlations between personality traits and the type of symptom shown were calculated for 400 mainly neurotic patients by Slater(11). The highest correlation ($r=0.76$) was between obsessional traits and symptoms, other correlations ranging from 0.5 for both hysterical and paranoid traits to 0.39 for depressive and 0.19 for hypochondriacal traits. This suggests that personality and illness are more closely related in obsessional than in other illnesses. Of the 120 obsessional patients investigated by Rüdin(10) 60% were insecure (selbstunsicheren) personalities before the illness, 30% were not, and 10% had compulsive traits in childhood but no other personality deviation prior to the onset of symptoms. Müller(9) confirmed the absence of the obsessional personality in some of his series of obsessional patients, but considered that the more severe the abnormality of personality structure the more severe was the course of the illness.

Lewis(7) gave figures neither for the conventional obsessional traits nor for his own typology in his 50 patients but thought that the personality might be as common in other groups of psychiatric patients since one third of his depressive patients showed obsessional traits and an even higher proportion of those with agitated depression.

While there is evidence that obsessional personality traits are of frequent occurrence in obsessional illness, there is a dearth of information on the incidence of the personality traits Lewis put forward and no comparisons of the two have been made.

METHOD

In the course of a study of the natural history of obsessional illness in 89 inpatients of a mental hospital, ratings were made of the premorbid personality as described by the patients and their relatives. These patients were divided diagnostically into a nuclear group showing obsessional and compulsive symptoms in a sustained symptom complex with no evidence of psychotic disturbance of thought or mood, or organic nervous illness. Other groups comprised those with no compulsive actions (phobic ruminative group), those in which the pos-

sibility of schizophrenia had been considered but rejected, those with depressive features, and a miscellaneous group where obsessional symptoms were associated with other illness, notably organic nervous disease.

For the present purpose the total group of patients with predominantly obsessional symptoms will be divided into two, the "nuclear" group of typical obsessive-compulsive states being separated from the others.

The list of obsessional characteristics given by Lewis was used and patients were rated for the presence or absence of each of: excessive cleanliness, orderliness, pedantry, conscientiousness, uncertainty, inconclusive thinking and acting, and fondness for collecting things. "Marked obsessional traits" represents the presence of 5 or more of the 7, "slight" the presence of 2 to 4, and "not obsessional" the presence of none or only one of those mentioned. In each case an estimate was made of the applicability of each of Lewis's two descriptions. All these ratings were based on observations by psychiatrist and relatives and not on the patients' accounts alone.

In 12 cases the age of onset was so early that no adult premorbid personality could be said to have existed, and these were omitted. Of the remaining 77, 31 were "nuclear" cases.

RESULTS

Only 12 of the 77 (16%) show no obsessional personality traits (Table 1). Sixty-five

TABLE 1
INCIDENCE OF OBSESSIONAL TRAITS

	Nuclear Group	Others	Total
Not obsessional	4	8	12
Slight obsessional traits	17	24	41
Marked obsessional traits	10	14	24
Total	31	46	77

(84%) show at least two and 24 (31%) show more than five. Of these patients with severe chronic obsessional illnesses the majority have shown traits of the obsessional character prior to illness and the various items making up the obsessional character are frequently associated in the one person.

The incidence of obsessional traits in the nuclear group of typical obsessive-compulsive states is no different from that in the rest of the group.

Only 30 of the 77 (39%) have one of the personality types proposed by Lewis; the majority cannot be described in this way (Table 2). In the 31 severe obsession-com-

mon as "obstinate, morose, irritable" personalities, and 18 of the 20 show obsessional traits.

DISCUSSION

The expectation that severe cases, such as made up this series, would show frequent anomalies of personality structure is supported by the results. The obsessional personality traits are widely applicable to these patients. One of Lewis's objections to their use was the lack of evidence that they cohere; that a third of the patients show 5 or more of the 7 examined is proof that they do cluster together.

In these quantitative terms the conventional traits are twice as applicable as the two types of Lewis. However, Lewis described his types as occurring in chronic severe obsessionals who had shown symptoms since childhood. While this group is without doubt chronic and severe, the 12 cases who showed symptoms from childhood were excluded. This was done in order to obtain an account of personality prior to illness; for if an attempt is made to measure traits in the presence of illness the borderline between them becomes difficult to demarcate. It is difficult to decide when uncertainty and vacillation become pathological, when orderliness and a need to check become ritual, and so on. The decision to assess personality only prior to illness was the only means of avoiding this problem. If the terms used by Lewis have any value as descriptions of personality, they should be discerned in severe and chronic patients before illness; if they have not, they may originally have been descriptions of symptoms rather than of personality.

They are applicable in 40% of the patients. While not so prominent numerically as the conventional traits, their importance may lie in distinguishing different kinds of obsessional personality.

In contrasting the obsessional personality as described in 8 British and American textbooks with the anal-erotic character as described by Freud(2), Jones(5) and Abraham(1), the differences in emphasis were interpreted in terms of the success or failure of the integration of the traits into the total personality(3). The trait of orderliness, for instance, can

TABLE 2

Obstinate, morose, irritable	4	6	10
Submissive, vacillating, uncertain	8	12	20
Neither applicable	19	28	47

pulsive (the nuclear group) cases there was no suggestion that these types of character were more often present than in the rest of the group. In this group of patients the personality types of Lewis are not so applicable as the accepted traits.

The two methods of describing personality overlap (Table 3). The "uncertainty"

TABLE 3

RELATION OF LEWIS'S TYPES TO OBSESSIONAL PERSONALITY TRAITS

	Obsessional Traits None Slight Marked		
1. Obstinate, morose, irritable	1	8	1
2. Submissive; vacillating, uncertain	2	9	9
Neither applicable	9	24	14

and "inconclusive thinking and acting" items of the obsessional personality appear as "vacillating, uncertain" in the second of Lewis's types. This is reflected in the closer connection between obsessional traits and the "submissive, etc." group. The number of patients showing obsessional traits and also belonging to one or other of the Lewis types (27 out of 30) is significantly higher than the proportion (38 out of 47) of those showing obsessional traits in which neither Lewis type is applicable ($X^2=6.3$; significant at 0.02 level). "Submissive, vacillating and uncertain" personalities are twice as com-

be used successfully. Failure may be of two kinds: in one the patient suffers, in the second others suffer. One person may make his life a torment by his adherence to order, another may pride himself on his orderliness, imposing his standards on others and making them suffer. It was found that the psychoanalytic authors used terms implying success or a failure to get on with others (e.g. obstinate, power-loving, pedantic, avaricious). The obsessional personality descriptions laid more emphasis on the other type of failure: that in which the person suffers (e.g. indecisive, conforming, submissive).

Examining the two sets of terms used by Lewis it is clear that "obstinate, morose and irritable" are words implying that others suffer, while "submissive, vacillating uncertain" imply suffering for the patient. The division between them corresponds to the two types of failure already outlined. Their relative incidence is therefore of some interest.

Those who suffer are twice as common in this series as those who make others suffer. From a psychopathological view this is easily explained. The two forms of behaviour represent different methods of dealing with the same anxiety and insecurity, but making others suffer is more likely to be successful in avoiding neurosis than suffering oneself. One might be called psychopathic behaviour, the other neurotic. Accordingly those who suffer from their traits will be overrepresented in a series of obsessional patients. To establish this with certainty it would be necessary to have information about the incidence of the two types in the normal population.

SUMMARY AND CONCLUSIONS

An examination of pre-morbid personality in 77 inpatients with severe obsessional

states shows that obsessional personality and illness are intimately connected and that the conventional obsessional traits, present in 84% of the group, justify their general acceptance when re-examined in their original setting. The description by Lewis of "obstinate, morose, irritable" and "submissive, vacillating, uncertain" types was applicable in only 39%, but the results suggest that certain obsessional traits may predispose to obsessional illness more than others.

CARDIAC ARREST AND ELECTROSHOCK THERAPY

GENEVIEVE A. ARNESON, M.D., AND TARVER BUTLER, M.D.¹

Over the past 5 years at Charity Hospital we have had 3 deaths attributed to electroshock treatment. This represents a mortality rate of 0.15% per patient and 0.015% per treatment. Two of the deaths were definitely felt to be secondary to cardiac arrest.

Although the mortality rate is extremely low with EST, cardiovascular deaths usually head the list, followed by cerebral and respiratory deaths. Following our first cardiac arrest, a thoracotomy set was made available in our EST treatment room. The following case report involves a cardiac arrest following EST which was treated with direct, manual cardiac massage.

Case Report.—A 24-year-old C.M. admitted to Charity Hospital on February 4, 1960, had a 3 week history of "nervousness," inability to sleep, feelings of unreality, ideas of reference, persecutory delusions, multiple, bizarre somatic complaints, and auditory hallucinations. Diagnosis was acute schizophrenic reaction, paranoid type. This was the patient's first episode of overt psychiatric illness. Physical examination including routine laboratory examinations, chest and spinal x-rays, and electrocardiogram were reported as within normal limits. On February 27 the patient was started on a course of EST. Each treatment was preceded by routine medication of 2 mg. levo-hyoscyamine (Bellafoline®), intramuscularly. After the 3rd treatment he complained of midback pain. Although spine x-rays were negative, he was commenced on 15 mg. Anectine i.v., with succeeding electrical treatments. By March 28, 1960 he had received 16 treatments with good improvement. On this date the patient received his 17th treatment. He appeared to recover and respond in the usual manner following the treatment, and he was taken to the recovery room. About 20 minutes later when the aide attempted to rouse the patient for return to the ward, he responded briefly and then became unresponsive and apneic. Immediate steps were taken to establish an airway and begin artificial respiration, while the patient's personal physician was called. The doctor came immediately but by this

time at least 10 minutes had elapsed. The patient had no pulse. Because of the initial excitement and confusion getting artificial respiration started, we had no idea exactly how long he had been in cardiac arrest so that immediate thoracotomy was instituted. The heart was found to be in asystole and cardiac massage was begun. A few minutes following massage, a weak, but spontaneous heart returned. Shortly afterwards an intravenous saline drip was started and ephedrine was given i.v. The heartbeat became stronger and more regular. An intra-tracheal airway was inserted and patient was respired with the bag breathing apparatus. Spontaneous respiration did not return although the heart continued beating. After 2 hrs. he was transferred to a Drinker respirator. Spontaneous respiration never did return and it was apparent that the respiratory center had sustained irreversible damage secondary to cardiac arrest and the accompanying anoxia. An EEG taken on the patient at this time was reported as, "compatible with non-functioning of the cerebral cortex." The patient died approximately 12 hours after thoracotomy. The gross post-mortem examination was negative except for the results of thoracotomy, tracheotomy, manipulation of the chest wall, and massage of the heart.

DISCUSSION

Neither of our patients was considered a "poor risk" patient and a number of "poor risk" patients have received EST without incidence. In our experience, the fact that a patient is in apparent good physical health, free of any cardiovascular disease or abnormality, does not mean that he may not suffer a cardiac arrest associated with EST, or on the other hand, a "poor risk" patient is any more prone to this catastrophe.

This brings up the possible physiological mechanisms for the cessation of the heart beat during this type of treatment and possible prevention of it.

There is no question that the grand mal seizure following the electrical stimulation of the brain in EST is accompanied by a marked vagal discharge. Richardson, *et al.*, (6) report vagal arrhythmias in 30% of patients receiving EST under anesthesia. On

¹ Department of Psychiatry and Neurology, Louisiana State University School of Medicine and Charity Hospital of Louisiana, New Orleans, La.

EKG tracings these were characterized by marked slowing and occasional standstill of the heart. However, according to the authors, adequate atropinization of patient (2.4 mg. or 1/25 gr. atropine), prior to treatment will completely block the cardiac portion of the vagus nerve.

At present, we routinely use levo-hyoscyamine as the antisialagogic vagolytic agent in the premedication of patients receiving EST. As reported by Trotti and Adriani(7) the antisialagogic effect of this drug is about twice that of atropine. The vagolytic effect on the heartbeat is about the same, i.e., equivalent doses of atropine and levo-hyoscyamine produced average pulse increases of 21 beats and 27 beats respectively.

There is no question that patients receiving EST should be premedicated with a suitable vagolytic drug and receive dosages of the order mentioned above. Conventional adult dosages of atropine (1/100-1/150 gr.) are not sufficient. Inadequate atropinization as an etiological factor in cardiac arrest associated with EST is a definite possibility although, as in our case, not the only factor.

Some of the EST deaths reported in patients who were simultaneously on one of the sympatholytic ataractics might operate in a similar manner. In this situation the patient receives a marked parasympathetic stimulation via the EST when he is already in a state of parasympathetic dominance secondary to the medication. Brachta and Hes(2) reporting on an EST death of a patient on 5-15 mg. reserpine per day, suggest that the parasympathetic overactivity and the sympathetic inhibition produced by Reserpine, plus the stress of EST, was enough to overwhelm the sympathetic regulatory mechanisms so that death ensued. Our first patient with cardiac arrest was on high doses of chlorpromazine. As a result of this experience we no longer give EST to patients who are on phenothiazine medication. However, other therapists continue to combine tranquilizers and EST and have had no difficulty(1, 5).

Drake and Ebaugh(3) report a case of an undiagnosed pheochromocytoma where patient was treated with EST and expired via cardiac arrest. This, in spite of an increased availability of sympathetic neuro-

hormones. In addition, Wilkinson(8) has described how patients vary in their pre-EST autonomic symptoms as well as their autonomic responses to EST not only among separate individuals but in the same patient from time to time. Apparently the explanation of cardiac arrest during EST is not a simple autonomic imbalance, or at least alternative explanations probably exist.

We are thus left in the rather disquieting position of:

1. Being unable to predict or anticipate a cardiac arrest associated with EST, at the present time.

2. Cardiac arrest does occur in conjunction with EST. Death of the patient results unless an adequate blood pressure can be maintained until the heart resumes its normal beat.

3. There are no certain preventative measures. (a) "Adequate" atropinization might be of some help in preventing cardiac arrest but this is not proven. (b) Avoidance of concomitant treatment with sympatholytic tranquilizers also may be helpful in preventing cardiac arrest but this also is not proven.

4. Until recently, failing a smart rap on the chest wall, the usual method of treating a cardiac arrest was via thoracotomy and cardiac massage.

While thoracotomy and direct, manual cardiac massage are dramatic and heroic measures, they are extremely traumatic events for patient, his relatives, and the doctor. Temporizing or hoping something will happen also does not work. Something has to be done and fast. The usually accepted time limit is 5 minutes before irreversible brain damage occurs.

First, all physicians who utilize EST as a treatment procedure must be aware that cardiac arrest can and does occur and must recognize it when it does.

Second, they must be able to treat it, preferably in a less fearsome and traumatic way than manual cardiac massage.

Recently, Kouwenhoven, Jude, and Knickerbocker(4) reported a method of closed chest cardiac massage which they have found effective in maintaining blood pressure and hence blood supply to the vital structures of the C.N.S. until, and if, the

heart resumes its beat. Their method is as follows :

With patient in a supine position ; preferably on a rigid support, the heel of one hand with the other on top of it is placed on the sternum just cephalad to the xiphoid. Firm pressure is applied vertically downward about 60 times/minute. At the end of each pressure stroke the hands are lifted slightly to permit full expansion of the chest. The operator should be so positioned that he can use his body weight in applying the pressure. Sufficient pressure should be used to move the sternum 3 or 4 cm. towards the vertebral column.

Closed chest cardiac massage provides some ventilation of the lungs and if there is only one person present in a case of arrest, attention should be concentrated on the massage. If there are two or more persons present, one should massage the heart while the other gives mouth to nose respiration.

This method has recently been utilized successfully in the Charity Hospital surgery. We feel that it could be effectively utilized in patients with cardiac arrest following EST.

SUMMARY

A case report involving a cardiac arrest in a patient following EST is given.

Possible mechanisms and prevention of this cardiac catastrophe is discussed.

The possibility is raised that closed chest cardiac massage could be utilized effectively in cardiac arrest associated with electroshock therapy.

IMPROVEMENT—REAL OR APPARENT ?

A Seven Year Follow-Up of Children Hospitalized and Discharged From a Residential Setting¹

RUTH POWELL KANE, M.D., AND GUINEVERE S. CHAMBERS²

In the last few years, a number of studies have been reported which conclude that psychotherapy with children and adults is no more effective in producing change than non-intervention. Those of us engaged in psychotherapeutic treatment, rather than being disheartened by the results from these investigations, find ourselves searching underlying reasons for this lack of objective proof for what we see taking place clinically. While we do not agree with Eysenk's *intent*, we do agree with his statement from the 1952 report, that "figures fail to support the hypothesis" for effectiveness of psychotherapy and, herein, lies the source of the dilemma. Figures cannot capture the subtleties of improvement, even if we could succeed in isolating the countless dimensions of change to be measured.

Since functional illness is a social phenomenon, improvement is also socially determined. And it is this network of complex interactions that makes it next to impossible to quantify improvement in any way that will yield a true picture.

In this paper, we are focusing on some of these factors which operate in confounding the results in follow-up data, in addition to reporting on what has become of patients who have received treatment in a specific setting. We are not attempting to set any baseline or ceiling for evaluating degree of improvement, but rather view improvement as a qualitative change in a patient's ability to cope with his environment, irrespective of original diagnosis or extent of illness. In other words, we believe that, as in other branches of medicine, if, after treatment, a patient is more comfortable than before, he is improved. If, indeed,

he is only more acceptable to his family or if he lives more satisfactorily within an institution than he could have at one time in his history, then he is improved.

The subjects of this survey are the 24 children who have received treatment and have been discharged from the Children's Residential Treatment Service of Western Psychiatric Institute and Clinic in Pittsburgh. The 14 bed unit was established in 1951 for treatment, training and research purposes related to the total problem of emotional disturbance in childhood. Only children up to age 12 years, usually with intact families, were accepted for treatment. Initially, the program offered only residential care, but in 1956, day-care was added to the service. Patients from both types of service are included in this report.

Briefly, the treatment consists of : 1. Milieu therapy conducted by workers under close supervision of the training staff ; 2. Individual psychotherapy for each child ; and 3. Parent counseling in individual and group sessions conducted by psychiatric social workers.

Electroshock has never been administered and very little use has been made of drugs. Only 2 children of the 24 have ever received ataractic drugs, and in each case only for a short time ; both were diagnosed as childhood schizophrenia.

To assess the present status of each patient of the sample, a questionnaire was designed to be sent to the parents of all the children, whether living at home or in institutions ; in the latter instance, questionnaires were also sent to the institutions. The questionnaire was designed to reflect both objective and subjective reality. Informants were asked to judge easily observed, overt behaviors of the kind that would also be likely to have been recorded in hospital charts. The three main areas of inquiry were : 1. Individual adjustment ; 2. Social adjustment ; and 3. Health. These 3 areas were subdivided into a total of 13 specific items. For example,

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Respectively, psychiatrist and psychologist, Children's Residential Treatment Service, Western Psychiatric Institute and Clinic, Pittsburgh, Pa.

under "individual adjustment," inquiry was concerned with how well the child could dress himself, communicate ideas, and in general be responsible for his own executive functions. His "social adjustment" was explored for the quality of his relationships to family, community and school. The "health" category covered general physical condition and any use of drugs. Each item calls for three different types of information in the evaluation of a given skill. The informant first judges, by multiple choice procedures, whether the patient is doing as well, less well, or better than normal children of the same age, or whether this area had never been a problem in the child's symptom picture. If the child is seen as above or below average, the parent is asked in each instance, to present in free response form the evidence on which this judgment was based in space provided for "comments" immediately below each block of multiple choice items. And finally, a 5-point rating scale is provided to indicate direction of change, if any, in this skill since discharge. A blank page is attached at the end of the questionnaire and respondents are invited to communicate any additional information that they feel might be helpful, thus furnishing a fourth type of material.

This four-pronged approach to evaluation permitted the authors to analyze returns for inconsistencies in judgment that emerge when one method of report is compared with another in the process of judging a single skill. We anticipated that personal motivation might distort a parent's perception of his child. A parent might, for example, see his child as expressing his ideas better than others, but reveal when he explains, that what he has clung to as a source of personal comfort is merely the child's ability to communicate well in some bizarre autistic fashion. From experience with our parent group, we also expected disparities in the other direction, *i.e.*, a reluctance to admit openly that the child is as competent as he should be.

Verbatim descriptions of behavior relative to questionnaire areas, were extracted from hospital charts, for each child. These behavioral samples were taken from records for 3 distinct points in time: on admission, midway in treatment, and on discharge.

These excerpts were collected from the records by a third person before the questionnaires were returned and were used by the authors as the data to be compared with the current behavioral reports provided by the parents or other informants.

Returns were received from 18 out of the 24 families of discharged patients. Questionnaires were sent by registered mail; 5 were returned because whereabouts were unknown; one was received and ignored. This 75% return was better than expected. All 5 institutions contacted reported on the 7 of our former patients in their care. Currently, ages of the children range from 7 to 20 years. Fourteen of the 24 cases were diagnosed on admission as childhood schizophrenia and 7 of these were non-verbal. Of the remaining 10, 7 were diagnosed as psychoneuroses or behavior disorders and 3 as organic brain damage with secondary behavior problems. At discharge, 17 (71%) were rated as improved, and 7 unimproved, according to hospital charts.

Surprised as we were with the high rate of return, we were even more surprised by the results revealed by the questionnaire. Based on good solid behavioral descriptions supplied by the parents, rather than on the checked or rated items, 8 of the 13 children seen as improved by the parents, are remarkably improved in the judgment of the authors. Five of these were diagnosed childhood schizophrenic, 3 being non-verbal on admission and now talking well; and 3 were diagnosed as psychoneurotic. Twelve of the 13 cases, seen as improved by the parents, live at home. Nine of the 13 had the diagnosis of childhood schizophrenia; 4 of these were non-verbal and are now talking. Restated, three-fourths of these childhood schizophrenics are seen by their parents as improved. Least improvement occurred in the organic group and most in the psychoneurotic group.

We have provided mimeographed sheets containing the finer numerical breakdowns to allow getting to the discussion of the interesting clinical impressions suggested by the qualitative features of various parents' reports. The questionnaire, as designed, proved to be very satisfactory in picking up inconsistencies in parental attitudes toward the child and in furnishing hints of the re-

lationship between these inconsistencies and the child's pathology. If this survey accomplished nothing else, it was well worth the effort, to have so completely satisfied ourselves that structured check lists or rating scales alone will not yield a meaningful picture of how well or badly a person is fitting into his society.

Among some of the over-all impressions that emerged from analyzing the qualitative aspects of the questionnaires were: that the parents of the children diagnosed as autistic tend to view them much as they are seen by clinicians and show internal consistency in reporting; parents of the brain damaged children both over-rate and show marked inconsistency in their ratings; parents of the psychoneurotic patients under-rate and are inconsistent; while the parents of the children diagnosed as childhood schizophrenics and more like adult schizophrenics in symptomatology, produced the most grossly distorted and inconsistent pictures.

We reiterate that we are only presenting these as "hints" of relationships. But that these relationships are even suggested in a sample of so few cases makes it seem worth while to throw them out for speculation as possible hypotheses to be tested on other samples.

Our first notions about the possible implications of such a breakdown have to do with the degree of responsibility that the parent may feel for precipitating or contributing to the child's illness. Since so much disagreement remains about the causal factors in infantile autism, the parents, at least in our setting, are told that the cause is unknown. Perhaps, with this cushion against feelings of involvement in the illness, they can see what is going on with their child without needing to distort or deny.

In contrast, the parents of the brain-injured children, who rate them as much better than they really know them to be, may feel that in some way they are guilty of not having given the child adequate physical protection, even when the condition was totally beyond their control. The reaction seems to be one of overcompensation and the message they are trying to convey is: "See how well my child is because I have taken such good care of him."

Degree of involvement of the parents in the illness of the neurotic child is clearly spelled out to them in any treatment program. In modern America, even in very unsophisticated layers of society, there is recognition of the significance of psychological insult. And though these parents may not consciously acknowledge their involvement, that they are aware seems to be reflected in their need to deny the competence that they actually report. They *need* to see the child as incompetent to keep the family dynamics in equilibrium.

The parents of the verbal schizophrenic children are similar in their ratings to the parents of the neurotic children in that they too tend to under-rate, and again, out of need to maintain the family balance. But they are dissimilar in that instead of just overlooking the contradictions in their evidence, they use fantastic logic to distort the meaning of the behavior that they cite. They *must* keep the child sick.

Distortions in reporting occurred most frequently among families where the history clearly identified gross involvement on the parents' part in precipitating the illness and least frequently among those with least involvement such as adoptive parents or ones who had not had early responsibility for the child as in cases of divorce and remarriage.

How satisfied the parents are with arrangements made for the child following discharge also seemed to color their answers to the questionnaire. In one case where the child had to be discharged because of age and no other facility could be found for continuing treatment, the parents, still angry at us, could only minimally comply on the evaluation task. In contrast, another family, extremely grateful to us for the excellent results obtained, wrote volumes of material. Still another family, dissatisfied with the present resources available to them, gave a glowing, and highly inaccurate, appraisal of the child in the hope that we might readmit him.

Another impression that emerges from the qualitative material uncovered in this survey, concerns environmental factors that influence outcome of illness. One girl, who was discharged as improved, is now at home in poor condition awaiting institution-

alization. An outside agency gave us a picture of total chaos within this family. Gradually, she gave up in the hopeless struggle to adjust to this pervasive confusion. The questionnaire from the family included the contradictory statements that she was much improved and that she was awaiting institutionalization.

Expectations for the child by those immediately involved with him also are a big factor in the eventual outcome of his illness. One of the formerly autistic non-verbal boys who is now verbal and doing exceptionally well is a good case in point. Although the parents had given up all hope for his recovery when they were told that he was both brain damaged and retarded, a nurse on the service insisted that this was a bright, emotionally disturbed child, and devoted herself to proving it. When he was returned to his family as dramatically improved, they were apparently able to sustain this improvement when given a new set of expectations.

And finally, to illustrate how social factors play a role in adjustment: one boy who received the American Legion Award in eighth grade for the best all-around student was proudly credited by his father with being the most "popular boy" in the class. The boy corrected him by saying, "You mean, I'm the least unpopular one." Here he clinically demonstrates the uncanny insight and unacculturated honesty of the true schizophrenic, but in this case, he is accepted by his society for his intellectual power and is given a citation. Again, we point out that improvement is determined by the environment and not by clinically established norms.

SUMMARY

This survey revealed a more hopeful outcome for this group of seriously sick children than previous reports have suggested. It is gratifying to find that so many are doing well and that others, doing less well, are so comfortably absorbed by their families. Most encouraging of all are the reports on the 4 non-verbal autistic children who now talk and are active in society outside the home. This is especially heartening when one considers how late in life it was before any intervention occurred for some of these

children. Outcome is related not only to original diagnosis but also to a complex of attitudinal and social factors. In many cases, one is left to conclude that the critical elements in improvement can never be isolated. Or, sometimes, improvement, like beauty, lies in the eye of the beholder.

DISCUSSION

FRANKLIN G. EBAUGH, M.D. (Denver, Colo.).—It is a privilege to comment upon a paper which makes such timely inquiry into a group of variables in human adjustment which have plagued therapists from the beginning. It is impossible to understand a patient without insight into the setting in which he must function, and too often it is equally impossible to gain an objective, yet empathically meaningful view of that setting. As physicians for the mentally ill, we, too, are defined by our "social climate." With increasing public awareness of mental health and illness, and strong medical focus on treatment of the "whole patient," these questions about the *milieu* of emotional illness becomes ever more pressing.

Fortunately we now realize that the psychotic, even the non-verbal, highly autistic child who does not seem to have formed initial lines of communication, is strongly and continuously influenced by his environment—in a most dynamic sense. This is one of the important implications in the data which Drs. Kane and Chambers present. Improvements occurring in children removed from "sick families," the occasional regression of improved patients upon return to their original environment where the pathological influences operate, and the factors of family attitude and satisfaction with the post-hospitalization arrangements made for the child all point to the dynamic environmental influence on psychosis. The sound-deadened isolation of the schizophrenic child is only apparent, not real.

Polemic arguments about treatment methods—psychotherapeutic, vs. physical, vs. "vitamin pills dispensed with a smile"—are, like speculations about "spontaneous recovery," only a testimony to how little real knowledge we have about the laws of interpersonal communication. By emphasizing this, and by focusing on assessing the interaction of family relationship variables, the authors have made a decided contribution. Implicit in their research report, too, is recognition of the fact that the study of human behavior remains on the first step of the ladder of scientific investigation. No amount of rigidly fragmented "experimentation" in human reactions can change or deny this. Only one

procedure can change it : observation and more observation. As the authors point out, their *ad hoc* quantifications and notes are more meaningful than the pre-categorized data collected via rating scales and multiple-choice means. My comments are not to be interpreted as a negation of sound experimental control, of course, but only as a mild reminder of the values to be found in the childlike curiosity from which most of the basic facts of our better-developed sciences are derived.

Relevant to this entire subject of methodology, observation, and psychotherapy with schizophrenic patients is a striking experiment in "family unit therapy" reported by Dr. Murray Bowen in a 1959 publication entitled, *Schizophrenia, An Integrated Approach*, and edited by Alfred Auerback. For purposes of study, fathers, mothers, siblings, and the schizophrenic patient in 4 separate families, lived together as a family unit on the ward in a research center. The family had entire responsibility for the care of the ill member, and carried on their usual outside activities as normally as possible. One family remained there for 2½ years; all periods of residence were long. Six other families participated on an out-patient basis.

The theoretical hypothesis regarded the schizophrenic symptoms in the patient as a manifestation of an active process that involved the entire family. A psychotherapeutic ap-

proach consistent with the working hypothesis required that the family members attend all psychotherapy hours together. An attempt was made to observe and relate to the family unit rather than to the individual family member. Some of the broad patterns of relationship functioning observed included a condition termed, "emotional divorce," between the parents. The family conflict seemed to remain in the father-mother-patient triad; other siblings had, perhaps at the expense of the patient, divorced themselves from participation and found their satisfactions outside the family unit. The most common family configuration was one in which the overadequate mother was attached to the helpless patient and the father remained peripheral to this intense twosome. If, during the psychotherapeutic process, the passive parent became more adequate, the formerly overadequate parent seemed to shift to the vacated position, thus maintaining the neurotic balance of the family. In those families in which parents could resolve the emotional divorce, the psychotic patient began to change toward more mature functioning.

It is in contributions such as the one just cited, and the work of Drs. Kane and Chambers, that we shall begin to understand the "ground rules" of interpersonal relationships—the ways in which they not only produce, but also perpetuate, mental health and illness.

PSYCHIATRIC FACILITIES IN CHICAGO

FRANCIS J. GERTY, M.D.¹

The last report on the Psychiatric Facilities of Chicago and surroundings was made at the annual meeting of the American Psychiatric Association in Chicago in 1957. At that time construction of the Illinois State Psychiatric Institute was in progress. The Institution is now functioning according to the plan formulated by the members of the Illinois Psychiatric Council during the preceding years.

Each of the 5 medical colleges, Illinois, Loyola, Northwestern and the University of Chicago and the Chicago Medical College supervises teaching and research in separate units of the Institute. The same is true of the Psychosomatic and Psychiatric Institute for Training and Research of the Michael Reese Hospital and of the Mental Health Services of the Department of Public Welfare of the State of Illinois. Approximately 60 patients have accommodations in each of these units. Treatment supervision for each unit is under the charge of physicians paid by the Department of Public Welfare but working under supervision of the Head of the Department of Psychiatry of each of the participating institutions. Consultants are provided from the same sources. Undergraduate medical students are taught in the wards of the Institute. There is a 3-year approved residency training program in psychiatry. The Institute is fully equipped for both psychological and physical means of research. A large auditorium is provided for holding medical meetings.

On July 1, 1961, the new State Pediatric Institute will be opened. This Institute is for treatment, teaching and research with mentally retarded children. It is intended that the Institute will accommodate between 500 and 600 children. Doctor Herbert Grossman

will serve as Director. It is intended that the Pediatric Institute, located adjoining the Illinois State Psychiatric Institute will have activities somewhat parallel to those of the State Psychiatric Institute.

In November, 1960, the electorate of Illinois approved a bond issue of \$150,000,000.00 for new construction and rehabilitation of the institutions of the Department of Public Welfare. Most of the institutions serve patients with mental illness and the major part of the expenditures will be for the improvement of the physical facilities of the mental health services. Governor Kerner was elected by a large majority of votes on a platform which had, as one of its chief planks, the improvement of services to the mentally ill. Legislation has just been introduced to provide for a separate Department of Mental Health under the direction of a psychiatrist. Included in the proposals to the legislature is a recommendation for an increase in the budget of the Department of Public Welfare of approximately \$39,000,000.00 intended chiefly for the provision of increased personnel in the mental hospitals and schools for the mentally retarded. It is intended to increase the number presently employed by over 4000 persons.

At the time of the 1957 report, construction of the new Presbyterian-St. Luke's Hospital was under way. The Hospital has been completed and its psychiatric unit of 72 beds which occupies the 12th and 13th floors of the new building, has been in operation for nearly 2 years.

The other psychiatric facilities reported upon in the American Journal of Psychiatry in 1956 and 1957 at the time of the last annual meetings of the Association in Chicago, still continue in operation and this report will serve as an appendix to them.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

THE EFFECT OF MONASE IN DEPRESSIVE STATES : A MULTI-BLIND PILOT STUDY

H. AZIMA, M.D., DOROTHY ARTHURS, R.N., AND A. SILVER, M.D.¹

The purpose of the present paper is to present preliminary trial with a new amine-oxidase inhibitor in the treatment of depressive states.

The setting in which Monase² was administered is designated as "multi-blind" because it contains the following characteristics: 1. Pharmacotherapeutically blind unit; this consists of part of the research service at the Allan Memorial Institute where all pharmacotherapies are blind, i.e., the members of the service team (6 psychiatrists, 1 psychologist, 1 occupational therapist and 1 research nurse) are unaware of the nature and the regime of the drug administration. The research nurse distributes the drugs and adjusts the dosage according to the patients' response in consultation with the head of the unit. On the average, 5 new drugs and 1 or 2 placebos (potent and inert) are used simultaneously in this unit. 2. Multiple observers; this consists of the use of all members of the team for the final assessment of any given substance. The individual assessments are made according to a simple rating scale which in cases of depression consisted of the following items: behavioral observations (retardation, overt depressive features, number of hours of sleep, and weight loss); experiential observations (subjective feeling of depression, guilt feeling and feelings of hopelessness). Each item is rated from 1-4 (nil to marked) and the final assessment is an accumulation of these ratings.

Under the above regime, 30 patients (depressed) received Monase with an average daily dosage of 60 mg. (maximum 120

mg., minimum 30 mg.) for an average length of 20 days (maximum 30 days, minimum 6 days). There were 20 females and 10 males; average age 46. Diagnostically, they consisted of 13 neurotic and 17 psychotic depressions (5 involutional, 3 manic-depressive, 6 associated with schizophrenic symptoms and 3 senile).

A relatively identical group of 30 other depressed patients received placebo for an average period of 10 days. There were 18 females and 12 males; average age 48. Diagnostically they consisted of 13 neurotic and 17 psychotic depressions (6 involutional, 1 manic depressive, 6 associated with schizophrenic symptoms and 3 senile).

Fifteen patients (8 neurotic, 7 psychotic depressions) showed significant improvement, i.e., from moderate to marked (50%) in the Monase treated group in contrast with 4 out of 30 (13.3%) in the placebo treated group. The reason for the unexpectedly low responsivity of placebo group seemed to be the great intensity of depressives treated as inpatient, the relative impurity of depressions and the inclusion of mild improvements into nil category.

Side effects were, on the whole, relatively few and not very severe. These consisted of feelings of "jumpiness," increase in anxiety and irritability in 5 patients, sleepiness in 2, dizziness in 2, headaches in 2, nausea in 1, and blurred vision in 1. Biochemical studies consisting of white blood count and differential, alkaline phosphatase, transaminase, and urine analysis, once weekly, T.P.R. and blood pressure b.i.d did not show any abnormalities with the exception of 1 case because of leukopenia (WBC 3000) in which the drug was discontinued and leukopenia disappeared. In the placebo group, 1

¹ From McGill University, Department of Psychiatry and Allan Memorial Institute.

² Monase is manufactured by Upjohn Company.

patient developed marked urticaria the second day.

- From the above data, it was concluded that even though the effectiveness of Monase, percentagewise, was only 50%, but

due to the 13.3% placebo results in identical cases and due to the multiblind nature of the research setting, the drug could be classified as an adequately potent antidepressant.

A STUDY OF COMBINED THERAPY WITH STELAZINE AND "PARNATE" (SKF 385) IN CHRONIC ANERGIC SCHIZOPHRENICS

W. J. BUFFALOE, M.D.,¹ AND M. G. SANDIFER, JR., M.D.²

Because of the current interest in combinations of a "tranquilizer" and an "energizer," a trial was made of a combination of Stelazine with Parnate (SKF 385), a new antidepressant. (Parnate is an amphetamine derivative and a monoamine oxidase inhibitor.) The patients selected for the study were 20 male schizophrenics with an average age of 48 years (range 36-56) and an average hospitalization of 22 years (range 13-33). Primary manifestations of psychopathology were disinterest and inactivity. No physical methods of treatment had been employed for several years, but most of the patients had been on a phenothiazine derivative prior to this study. All patients were on the same closed ward which housed 28 patients. A remotivation program with outside recreational and occupational activities had been under way for two years, but results had remained at a plateau for several months.

All 20 patients were placed on Stelazine for five weeks, during which time the attendants made weekly hospital adjustment ratings. After the fifth week the ratings were averaged for each individual. On the basis of these scores, the patients were then divided into two groups of 10 each, using paired comparisons to distribute observed psychopathology equally in the two groups. Group A then received both Stelazine and Parnate for 5 weeks while Group B continued on Stelazine alone. Even though each patient received active medication, placebos, identical in appearance, to the

Stelazine and Parnate, were used where necessary to insure that each patient received two capsules t.i.d.³ The dosage of Stelazine was individually adjusted by the ward physician (W.J.B.), according to therapeutic need and the presence of side effects. Dosage of Stelazine ranged from 2 mg. (in one susceptible patient) to 30 mg. daily, with an average of 20 mg. Parnate was given in the dosage of 30 mg. daily. No other drugs were used.

Screening for possible toxic effects included clinical examinations, blood counts, urinalyses and liver function studies, all with essentially negative results. Weight was unaffected; Parnate patients gained an average of one pound. No patients were hypertensive, and blood pressure was the same in the two groups (average 103/69 with Stelazine and 109/73 with Stelazine and Parnate). One patient, who had a blood pressure of 90/60 on Stelazine, fainted in the fifth week on Stelazine and Parnate. Blood pressure at that time was the same, 90/60. No persistent insomnia was noted.

Possible therapeutic effects were judged by weekly hospital adjustment ratings made by an attendant (unfamiliar with the experimental design) on each of the day shifts. This rating device is an abbreviated form of the Hospital Adjustment Scale.⁴

³ Appreciation is expressed to Smith Kline and French for preparing and furnishing the medications in identical capsules.

⁴ The abbreviated form, consisting of 25 items of the original 90 of the HAS has proved to be a useful and accurate assessment of hospital adjustment, and will be further described in a subsequent publication by Dr. Richard Dunham, Chief of Psychology, Dorothea Dix Hospital. Appreciation is expressed to Stanford University Press and Dr. James T. Ferguson for permission to use this scale.

¹ Assistant Superintendent, Dorothea Dix Hospital, Raleigh, N. C.

² Director of Research, Hospitals Board of Control, Raleigh, N. C.

TABLE 1
Culturally "Right" Scores on the
Abbreviated Hospital Adjustment Scale
(Possible Maximum=25)
10 Subjects Each Group

	WEEKS 2 THRU 5	WEEKS 7 THRU 10
GROUP A	Stelazine 9.8	Stelazine and Parnate 9.7
GROUP B	Stelazine 10.5	Continued Stelazine 12.0

By prior arrangement, the average for weeks 2-5 and 7-10 was selected for determining results. These are shown in Table 1. The maximum pathological score is 25, and the lower the score the better the hospital adjustment. Differences between the Stelazine and Stelazine-Parnate groups are inconsequential ($p > .20$). This is compatible with the direct observation of the two physicians.

Our conclusion is that, while Parnate appears to be non-toxic and may be beneficial in other clinical states, a Stelazine-Parnate combination did not give therapeutic benefits over Stelazine alone in this group of chronic anergic schizophrenic patients.

FLUPHENAZINE IN PRIVATE PSYCHIATRIC PRACTICE

LAURA E. MORROW, M.D.¹

The efficacy of certain phenothiazine derivatives in the treatment of psychotic patients (1-5) has stimulated interest in new members of this series as they have become available for clinical trial. Among those most recently introduced is fluphenazine, a trifluoromethyl hydroxyethyl piperazine propyl derivative of phenothiazine. Fluphenazine is the most potent of the phenothiazines yet developed (6-8) with a rapid and sustained tranquilizing action (6-7) and other pharmacologic properties characteristic of this group of compounds (9). Over the past two years fluphenazine has been employed in the treatment of ambulant patients with a variety of mental disorders who were referred to this office for study. During that period fluphenazine proved to be a very useful drug, especially helpful in facilitating psychotherapy, even of those patients who had resisted usually adequate psychotherapy prior to its use.

METHODS AND MATERIALS

A total of 174 non-hospitalized patients was treated with fluphenazine; 16 were children, age range 4 to 16 years; 158 were adults between 19 and 79 years of age. All had psychiatric disorders, primarily chronic in nature, but in most cases they presented

acute symptoms for which treatment was sought. Sixty-nine of the 174 patients displayed psychotic manifestations such as confusion, delusions, hallucinations, ideas of reference, withdrawal and/or morbid depression or morbid fears, while 105 presented symptoms of emotional disorders characterized mainly by anxiety, tension, or depression. All but a few of the psychiatric patients had received previous psychiatric therapy which had included other tranquilizing agents: about one-third had undergone electroshock therapy, and most of the emotionally disturbed patients had also been treated previously with tranquilizing drugs as well as psychotherapy.

Fluphenazine was administered either intramuscularly or orally, usually in doses ranging from 0.5 mg. to 2.5 mg. once or twice a day. In only 5 cases did the daily dose exceed 5 mg. with 2 patients receiving 7.5 mg. and 3 being given 10 mg. of fluphenazine. Treatment was continued in the individual cases from 1 week to 24 months. The majority were treated for at least 2 months, and half were continued on the drug for at least 6 months, while approximately 20% received treatment with fluphenazine for a year or more.

Other medications such as amine oxidase inhibitors, sedatives, or antidepressants, as well as antiparkinsonian drugs, were pre-

¹ 197 Passaic Ave., Passaic, N. J.

scribed as indicated. In some cases, other tranquilizing drugs were also added to the regimen, and each patient received psychotherapy throughout the period of observation.

RESULTS

Of the 174 patients, 7 were treated for too short a period to permit evaluation of the therapeutic results. Of the 167 patients in whom the results were evaluated, 117 (70%) showed a satisfactory response with complete or almost complete disappearance of the symptoms for which they had presented themselves for treatment. Among those showing a satisfactory recovery from the present attack of illness were a number with long histories of hospitalization during which they had undergone electroshock and other types of psychiatric therapies. Essentially the same proportion of psychotic patients responded satisfactorily as did those with emotional disorders. An additional 22 of the 167 patients who were evaluated displayed some relief of symptoms and increased cooperativeness after treatment with fluphenazine but in these the response was considered to be only "fair." The remaining 35 patients showed little or no improvement.

No reactions whatever to fluphenazine developed in 131 of the 174 patients, all unwanted effects being observed in 43, with those most frequently being wakefulness (38) and parkinson-like symptoms (33). In most cases all of the reactions could be controlled by reducing the dose and/or adding methanesulfonate (Cogentin) or other anti-parkinsonian drugs to the schedule, but in 14 the unwanted effects were so distressing that the drug was discontinued. Those effects which required withdrawal of treatment included "rubbery" legs (1), tension (1), leg cramps (2), oculogyric crisis (1),

blurred vision (1), sore mouth (1), restlessness (1), nervousness (2), akathisia (3), and dyskinesias of the face (1).

CONCLUSIONS

Fluphenazine (Prolixin) is a highly effective tranquilizing agent which may be administered with safety to non-hospitalized patients with a variety of psychiatric illnesses. The drug is especially helpful in facilitating psychotherapy. The almost universal relief of gastrointestinal distress in the patients treated with the drug, the absence of skin rash or photosensitivity or of observable hepatotoxicity, and the low incidence of akathisia made the drug especially useful. A very pleasant side effect reported by many patients was a sense of alertness which was beneficial in those who had been on large doses of chlorpromazine. Some were relieved from long-standing migraine headache or severe headache associated with the menses. In several others, severe allergic manifestations such as urticaria disappeared.

IMPROVING INSULIN THERAPY WITH NEOSTIGMINE¹

AMEDEO ESPOSITO, M.D., AND IRVING D. ROSENBERG, M.D.²

One of the difficulties in insulin coma therapy is that the patient who has been

gavaged (to terminate the treatment) may go deeper into coma instead of regaining consciousness. For example, the technique of insulin coma therapy used in the New Jersey State Hospital at Greystone Park is

¹ The neostigmine used in this project was the Hoffman-La Roche product Prostigmine.

² 44 Maple Ave., Morristown, N. J.

as follows. The patient's insulin dosage is gradually raised to the level where he goes into hypoglycemic coma 1 to 3 hours after the insulin injection as described by many authorities, including W. A. Horwitz(1), and he is allowed to remain in coma for progressively longer periods of time ranging from 5 minutes to 1 hour or so. The coma is terminated by gavage, consisting of instilling one quart of 40% sucrose via nasal tube into the patient's stomach. Ordinarily, the patient shows signs of coming out of the coma within 15 minutes (but, if not, he is given an intravenous injection of 50% glucose, 50 or 100 cc.). The sucrose is hydrolyzed by a specific enzyme (sucrase) into glucose and fructose(2) which are then absorbed by the small intestine(3). Sucrose, because of the inherent nature of the molecule, cannot be absorbed by the gastro-intestinal tract(4). Therefore, after gavage, the blood sugar level rises and the patient wakes up.

However, in about 5-10% of the cases, intravenous injections of glucose have to be used because the patient either goes deeper into coma or takes excessively long to come out of the coma. In these cases it was postulated that the patient has a low concentration or volume of sucrase, a prolonged emptying time of the stomach, or an impaired peristaltic activity of the gastro-intestinal tract leading to poor absorption of glucose and fructose. For such cases therefore, it was reasoned that, since neostigmine increases peristalsis(5) and shortens gastric emptying time, this might be a valuable drug in decreasing the number of intravenous injections that have to be given during ICT.

Three female patients and 1 male patient out of a group of 38 females and 23 males were found to require intravenous injections 100% of the time even though they had been gavaged during 3 to 8 previous insulin treatments. (Insulin coma treatments at Greystone Park are ordinarily given 3 days a week to the males and 3 days a week to the females alternately.) Therefore, 1 mg. of neostigmine was injected intramuscularly just before gavage to each of these patients. Two patients came out of the insulin coma

within 1 hour for the first time without intravenous injection of glucose, and the other two patients seemed to be in more shallow depths of coma than previously but had to be brought completely out of coma again by intravenous glucose. On successive treatment days, 1 mg. of neostigmine was given to those of this group who had come out of coma within 30 minutes of gavage, and the dosage was raised to 1½ mg. for the others. In addition, the neostigmine injection was given no later than 10:00 a.m. even if the gavage was performed later (the insulin injections are given at about 7:00 a.m. at Greystone Park). With this routine for the next 4 weeks, all 4 patients mentioned above have been routinely coming out of coma without intravenous injection, and the number of intravenous injections required for each ward therefore has been sharply reduced with a significant saving in time, effort, and expense.

SUMMARY

In insulin coma therapy, in those patients who regularly require intravenous injections of glucose to bring them out of coma, the intramuscular injection of 1 or 1½ mg. of neostigmine from 10 to 45 minutes before gavage with 1 quart of 40% sucrose resulted in a 100% elimination of intravenous injections required. This therefore is felt to be an important contribution to insulin coma therapy. In addition it may help materially in the re-establishment of insulin coma therapy at those mental hospitals where it was previously discontinued because of the greater number of personnel required to administer intravenous injections.

THE EFFECT OF MEPROBAMATE (MILTOWN®), RO 1-9569/12 (NITOMAN®), AND SCH-6673 (TINDAL®) ON THE ODOR OF SCHIZOPHRENIC SWEAT³

KATHLEEN SMITH, M.D.,¹ AND ALFONSO CORZO MOODY, M.D.²

These exploratory studies were conducted in order to determine whether various tranquilizers remove the characteristic odor noticeable in the sweat of certain patients with the schizophrenic syndrome(1). In 1956, Pennington suggested that the acrid "skunk-like" odor of 4 catatonic patients disappeared after treatment with meprobamate and that this might be due to relief of anxiety with a decrease in the amount of sweat produced(2). In 1960, Gouldman and Rutherford reported that a phenothiazine derivative, Sch-6673, appeared to abolish the body odor of schizophrenic patients and postulated that if this odor is a product of a characteristic metabolic disturbance in schizophrenia, then, Sch-6673 may modify the disturbance(3).

METHOD

Selection of patients. Five male schizophrenic patients with the characteristic odor in easily discernible amounts were chosen by 3 observers with two years' experience in discriminating this odor from other odors ordinarily present in sweat. These 5 patients have been observed many times in the course of other studies and have this characteristic odor 100% of the time, whether ex-

amined by a cotton ball underarm sniff test, sniffing of the residue on a watch glass after ether extraction, or by rat-conditioning methods.

The patients live on the same ward and have the same diet and level of activity. No deodorants are used. In each case the previous medication was discontinued for one week.

Meprobamate⁴ study. Patients 1 and 5 received Miltown® 400 mgs. q.i.d. for 3 days, 800 mgs. q.i.d. for 3 days and finally, 1600 mgs. q.i.d. for 14 days.

Ro 1-9569/12 study. Patients 3 and 4 received Nitoman® 50 mgs. b.i.d. for 3 days, 50 mgs. t.i.d. for 9 days, and finally, 100 mgs. t.i.d. for 7 days.

Sch-6673 study. Patients 1 and 3 received Tindal® 20 mgs. t.i.d. for 9 days followed by 40 mgs. t.i.d. for 14 days. Patients 2 and 4 received a Tindal® placebo during the same period. Two of the observers did not know which of the 4 patients were receiving placebo.

Test method. A cotton ball on the end of forceps was rubbed in each armpit and immediately sniffed by the 3 observers. Results were recorded on a 1 to 4 plus scale. Sniff tests were done when the patients were selected, one week after no medication,

AVE.	24.4	51.6	27.2	20.2	++++		

before beginning the drug, at 3-4 day intervals, and at the end of each study.

RESULTS

No essential change in the quality or quantity of the characteristic odor was detected during the various trials. When a bath had been given the night before, the odor was still prominent on the following day. The clinical condition of the patients was unimproved during each trial period. No toxic reactions occurred.

DISCUSSION

The clinical impression that Miltown® eliminated the characteristic odor of schizophrenic sweat was not borne out after a more systematic study. The findings concerning Tindal®, likewise, could not be substantiated when a more direct method of testing was used. Whether deodorants were used intermittently by the patients was not reported. Possibly an odor that was not the "characteristic odor" was being monitored. For definitive answers a direct

chemical test for the substance responsible for this odor is essential.

Additional clinical observations on some of the above patients who also received other tranquilizers are available. The characteristic odor was not eliminated by therapeutic dosages of reserpine (Anquil®), chlorpromazine (Thorazine®), trifluoperazine (Stelazine®), prochlorperazine (Compazine®), and meprobamate (Equanil®).

CONCLUSIONS

The administration of several classes of tranquilizers under standard conditions failed to eliminate the characteristic odor found in certain schizophrenic patients.

A FAILURE TO FIND DISTINCTIVE PERSONALITY FEATURES IN A GROUP OF OBESE MEN¹

NORRIS WEINBERG, Ph.D.,² MYER MENDELSON, M.D., AND
ALBERT STUNKARD, M.D.³

The notion that certain bodily illnesses occur in persons with specific kinds of personality has been a recurring theme in psychosomatic medicine. This notion was first systematically treated by Flanders Dunbar in her description of certain "personality profiles" purportedly specific for certain bodily illnesses. Since then a large number of reports have supported this specificity hypothesis, and have added to the types of personality characteristics and types of bodily illnesses which are held to be linked in some manner. Unfortunately, few of the purported body-mind relationships have

been tested and studies carried out with methodological rigor have sometimes not confirmed hypotheses based upon clinical impressions.

In view of the uncertain status of the problem of psychosomatic specificity, 18¹ obese men were examined for distinctive personality characteristics and were compared with a carefully matched control group. This appears to be the first such study of obese men. A similar study of obese women failed to find distinctive personality features.

METHOD AND MATERIALS

Eighteen markedly obese men, aged 19 to 60, were matched man-for-man for age, educational level, race, and referral source with 18 men of normal weight. Eleven of the subjects were consecutive obese male admissions to the General Medical Clinic of

¹ Supported in part by Research Grant M-3684 from the National Institute of Mental Health, U. S. Public Health Service.

² Current address: Department of Psychiatry, University of California Medical Center, Los Angeles 24, Calif.

³ Department of Psychiatry, University of Pennsylvania, Philadelphia, Pa.

a University Hospital, while 4 were consecutive male admissions to the Psychiatric Clinic of this hospital during the same period of time; 3 were medical students. Median percent overweight was 53 with a range from 22 to 78.

All subjects were tested individually with a wide range of standard psychological tests: 1. Four sub-tests of the Wechsler-Bellevue Adult Intelligence Scale—two Verbal tests (Information and Vocabulary) and two Performance tests (Block Design and Digit Symbol); 2. The California Psychological Inventory; 3. The Leary Interpersonal Check List; 4. The Taylor Test for Manifest Anxiety; 5. The Thematic Apperception Test; and 6. The Draw-a-Man Test.

The literature on personality characteristics of obese persons was reviewed and the most widely accepted and distinctive features encountered were stated in a series of 6 hypotheses. An attempt was made to differentiate the obese and control subjects with respect to these hypotheses. Differences between the groups were tested by the appropriate non-parametric statistic for related samples, usually the Wilcoxon Test.

RESULTS

Hypothesis 1. Obese men are more anxious and neurotically disturbed than non-obese men. There was no difference between the groups on the Taylor Test for Manifest Anxiety or on the Well-Being Scale of the California Personality Inventory.

Hypothesis 2. Obese men describe themselves as more dominant, status-conscious and self-accepting at a conscious level, but reveal themselves as weaker and more dependent at less conscious levels. There was no difference between groups on the Dominance, Status, and Self-acceptance Scales of the California Psychological Inventory, the Dominance score on the Leary Interpersonal Check List, the weakness and dependence measures derived from the Thematic Apperception Test, or the Draw-a-Man Test.

Hypothesis 3. Obese men obtain higher scores on the verbal than on the performance subtests of the intelligence test. The obese group did score significantly higher on the Verbal than on the Performance sub-

tests of the Wechsler Adult Intelligence Scale (mean Verbal I.Q. 115.7 vs. mean Performance I.Q. 105.4). Curiously, however, the control group revealed a similar disparity (mean I.Q. 117.3 vs. mean Performance I.Q. 103.5). The reason for the discrepancy between Verbal and Performance I.Q.s was not determined.

Hypothesis 4. Obese men are more intellectually conforming than non-obese men. There was no difference between groups on the Achievement for Conformity Scale of the California Psychological Inventory.

Hypothesis 5. Obese men describe their mothers as stronger than their fathers. There were no differences between obese and non-obese men in their descriptions of their parents on the Leary Interpersonal Check List.

Hypothesis 6. Obese men are more feminine in their interests than non-obese men. There was no difference between groups on the Femininity Scale of the California Personality Inventory.

The results were thus negative for the hypotheses tested. Furthermore, the psychological tests did not reveal differences of any kind between obese and non-obese groups.

DISCUSSION

The hypotheses utilized in the present study were constructed from reports on diverse obese populations which included women and children and which were studied by a variety of clinical and psychological means. Our findings do not, therefore, contradict the validity of the hypotheses when applied to other groups of obese persons studied by other means. They do suggest that such hypotheses do not apply to obese men. It is possible that a larger and more homogeneous obese male population might show psychological characteristics which would differentiate it from a non-obese group. The failure to find even suggestive points of difference, however, in conjunction with Friedman's similar negative results with obese women,⁴ indicates caution in accepting purported personality profiles in obesity.

⁴ Friedman, J.: J. Consult. Psychol., 23: 524, 1959.

SUMMARY

Eighteen markedly obese men were carefully matched with 18 men of normal weight

and given a battery of psychological tests. No distinctive personality features were found.

DYSTONIC REACTIONS PRODUCED BY TRANQUILIZERS

• SOLOMON HIRSCH, M.D., AND DORIS L. HIRSCH, M.D.²

Dystonia—one of the more interesting of the side effects of the phenothiazines—has been mentioned in the literature as easily confused with a variety of neurological disorders, but perhaps a more common error is to explain the dystonia as either a catatonic or conversion phenomenon. Since the patient receiving the tranquilizers is already disturbed and the clinical picture of the dystonia is so bizarre, the physician is sometimes able to fit the symptoms with the patient's psychopathology and to interpret them dynamically.

Because of the confusing picture presented by these patients, it is considered worthwhile to present in some detail descriptions obtained from several patients with dystonia.

Case 1.—A 20-year-old married woman with chronic anxiety became more acutely anxious 1 month post-partum and received prochlorperazine 10 mg. from her family physician. Twenty hours later both the patient and her family became greatly alarmed over her strange activity. Suddenly she began to stare at the wall, her mouth opened and her tongue protruded. With effort she was able to close her mouth. These symptoms subsided in a few minutes but recurred in several hours accompanied by marked terror. The family physician, suspecting a psychosis, requested a psychiatric consultation.

At the time of psychiatric examination the patient was extremely panicky with a pulse rate of 160, lowering to 120 with reassurance. Neurological examination was negative. Although there was evidence of chronic anxiety there was no gross evidence of psychosis. However catatonia was suspected. Because of the patient's fearfulness, hospitalization was contemplated but no bed was available at the time. The drug was discontinued. At home her

motor symptoms and anxiety gradually subsided without recurrence.

Case 2.—A 20-year-old nurse received triflupromazine 10 mg. I M. for nausea and vomiting of pregnancy. The following is her own description of the effects.

"Shortly after the injection I became very restless. The muscles twitched all over my body. In half an hour my head went back and stayed there unless I pulled it forward. My tongue felt swollen, my jaw twisted to one side, my teeth were clenched. My speech was slurred.

"The doctor (who felt the symptoms were functional) gave me an injection of barbiturates and although I was very irritated by his attitude I fell asleep and the symptoms went away.

"The next day I was very drowsy and had 2 half hour episodes during which my jaw seemed to go funny and tight. I walked and it went away. I had no trouble after."

Case 3.—A 21-year-old schizophrenic girl on chlorpromazine 25 mg. q.i.d. reported 2 episodes occurring in a 3-week interval:

"I just have to keep looking up. It lasts about an hour. My eyes go up. I can pull them down but they don't stay down. I can move my eyes from side to side but it's hard—it's hard to keep holding them down."

These episodes occurred although the patient was on Cogentin, subsided and recurred spontaneously. There were no other symptoms and she was able to carry on except that she was afraid to cross streets during an attack.

Several other similar cases were seen and it is of interest that in all these patients the original impressions of the physicians were that the symptoms were functional or emotional in origin.

In summarizing observations on these and other patients, some general characteristics are apparent. The dystonic symptoms are usually sudden in onset, occur episodically,

¹ Dept. of Psychiatry, Dalhousie University, School of Medicine, Halifax, N. S., Can.

are often of brief duration, and occasionally are under partial voluntary control. The latter results in the patient's description sounding peculiar. Pallor or flushing may accompany the other manifestations. Fear is usually marked and often accompanied by feelings of "going crazy" or peculiar explanations for the symptoms. Usually there are no signs of associated Parkinsonism.

Specific clinical manifestations of dystonia include tonic contractions and myoclonic twitches of any unilateral or bilateral muscle groups. Hyperextension of the neck and trunk with the spine curved backward from the hip, often associated with twisting of the head backwards or to one side and

jerkings of the head occurs. Spasm of the jaw muscles is common with the mouth either tightly closed or held fixedly open with protrusion of the tongue. Speech is difficult at times. Perioral tremors, mandibular tics, and difficulty in swallowing are often associated. Oculogyric spasms have been observed. There is a striking similarity at times to symptoms observed in post-encephalitic states.

Prompt recognition of the symptomatology of dystonia as an entity in itself is essential both to avoid diagnostic confusion with other psychiatric conditions and to facilitate treatment.

COMBINED TRANLYCYPROMINE-TRIFLUOPERAZINE THERAPY IN THE TREATMENT OF PATIENTS WITH AGITATED DEPRESSIONS

STANLEY LESSE, M.D., MEd. Sc. D.¹

This report is based on a 14-month study of 100 patients with severe agitated depressions who were treated with tranlycypromine (Parnate, SKF)² in combination with trifluoperazine (Stelazine, SKF)² on an ambulatory basis. Tranlycypromine is a very potent non-hydrazine monamine oxidase inhibitor structurally related to the amphetamines and has an enzyme blocking period which is quite short compared with other monamine oxidase inhibitors. The drug has very few side effects.

The study was limited to patients who manifested marked anxiety, agitation, restlessness, severe depression and feelings of hopelessness. The vast majority were completely incapacitated vocationally and socially.

This type of patient was selected because in my experience the antidepressant drugs currently available, when evaluated statistically, are of significant benefit only in patients whose depressions are associated with

a marked decrease in psychomotor activity (1). In a previous study I found that the tranlycypromine alone was of no significant help in the treatment of agitated depressed patients (2). Trifluoperazine alone was of inconsistent benefit in a parallel study of 50 agitated depressed patients.

METHOD

Sixty-nine patients were women, ranging in age from 25 to 78 years (all but 8 were over 40), 31 were men aged 35 to 72. The duration of treatment varied from 2 weeks to 14 months.

The usual initial daily dosage was 10 mg. of tranlycypromine and 3 mg. of trifluoperazine (administered in combination) t.i.d. (in particularly severe cases q.i.d.). If the agitation was not too profound, I found that the trifluoperazine could be reduced to 2 mg. 3 or 4 times per day. Therefore, the key to the amount of trifluoperazine used was the degree of agitation manifested prior to the onset of therapy.

Those patients who responded well began to show definite beneficial results within 24-72 hours. If signs of improvement were not forthcoming by then, it was uncommon for this combination of drugs to be helpful.

¹ From the Neurological Institute of the Presbyterian Hospital of New York and the Department of Neurology, Columbia University.

² The drugs used in this study were supplied by Smith Kline and French Laboratories, Philadelphia, Pa.

Fifteen of the 100 patients were considered as achieving an Improvement Rating of 1 (Excellent) while 48 showed an Improvement Rating of 2 (Good). Thus 63 of the 100 patients had complete or almost complete remissions of their depressions and were able to function vocationally and socially on a high level within 2 to 4 weeks after starting. Fourteen patients had an Improvement Rating of 3 (Fair) while the remaining 23 showed no improvement.

Seventeen of the 37 patients showing Improvement Ratings 3 and 4 (Fair and Poor) were schizophrenics. In general, patients ill for less than 6 months had the best results. There were 11 patients ill for more than 3 years, who had previously received active psychotherapy and organic therapies without definite help, whose response to the tranlycypromine-trifluoperazine combination was very gratifying (Excellent or Good).

In previous studies with antidepressant drugs, I found that an improvement in psychomotor activity preceded any improvement in the depressed affect (1, 2, 3). Fifty-one (81%) of the 63 patients who obtained satisfactory results in this study showed this pattern of improvement.

During the 14-month study, 16 of the 63 patients who initially had Improvement Ratings 1 or 2 had severe exacerbations of their depressions. In 6 of these the exacerbation occurred while they were on the drug combination, in the 10 others the drug had been discontinued. Six of these 10 had excellent or good results when the tranlycypromine-trifluoperazine combination was again administered.

Adverse side effects were minimal. Five patients had slight stiffness of their limbs if the trifluoperazine dosage was in the range of 12 mg. per day. This was relieved by the addition of methane-sulphanate (Cogentin, Merck). Two patients had orthostatic hypotensive reactions of sufficient degree to warrant stopping the drugs.

CONCLUSIONS

The tranlycypromine-trifluoperazine combination is of definite benefit in the treatment of patients with severe agitated depressions. In the author's experience this combination represents the only psychopharmacologic antidepressant that is of proven worth in this particular very prevalent clinical group. While others have reported that this combination has been of benefit in the treatment of chronic, regressed and withdrawn patients (4) and in chronic refractory schizophrenics (5), I have not found this to be true. To the contrary, this combination is of benefit primarily in patients with a marked increase in psychomotor activity.

CASE REPORTS

CHLORDIAZEPOXIDE HYDROCHLORIDE (LIBRIUM®) AND JAUNDICE: REPORT OF A CASE

JOSEPH CACIOPPO, M.D., AND SIDNEY MERLIS, M.D.¹

Severe untoward reactions have been infrequently reported with chlordiazepoxide hydrochloride (Librium®). This report is of interest because it is, to our knowledge, the first case in which jaundice occurred coincidentally with chlordiazepoxide therapy.

Case Report.—This 39-year-old white male patient had been hospitalized at Central Islip State Hospital for 6 months. He was diagnosed as schizophrenia, paranoid type, with convulsive disorder, grand mal and petit mal types. Since admission, partial seizure control was achieved on a regime of diphenylhydantoin sodium 90 mg. q.i.d., and phenobarbital 60 mg. q.i.d. On April 28, 1960, in addition to the above, he was given chlordiazepoxide in dosage of 25 mg. b.i.d. Five days later, on May 3, 1960, the patient was noted to have icteric sclerae and skin jaundice. There were no subjective complaints. The patient stated that he felt well and was quite unaware of this development. Laboratory workup on May 4 revealed significant hepatic abnormalities. He was admitted to the acute medical service

on May 6 in an ambulant and cooperative condition. Further questioning revealed that since beginning chlordiazepoxide therapy he had noted darkened urine and light stools. Physical examination was normal except for icteric sclerae and skin and a slight tenderness in the right hypochondrium. Fluoroscopy of the gastrointestinal tract was negative. X-ray studies for biliary tract calculi failed to reveal any abnormal calcification. The icterus persisted stubbornly and the overall clinical picture suggested an obstructive jaundice which seemed to run a prolonged course in spite of supportive therapy of fluids, withdrawal of drug and high vitamin intake. The course of the jaundice appeared to be unheralded by any infectious process, fever, general malaise or specific subjective complaints. The intensity of the jaundice as measured by the icteric index reached a peak 19 days after it was first noted. Abnormal laboratory findings persisted and gradually began returning to normal 3 weeks after the onset of his illness. Laboratory data are presented in Table 1. The patient continued jaundiced until June 18, a total of 58 days. He continued to receive diphenylhydantoin sodium and phenobarbital throughout his entire period of hospitalization except for a brief interruption of 4 days. Urine and stools

returned to normal color June 2. On June 27 the patient was transferred to a continued treatment building where he has remained well.

DISCUSSION

The frequency of side effects and toxic reactions to tranquillizer therapy has been well recorded. The significance of this report can only be established by subsequent experiences of others. In the case described here, it cannot be completely ascertained that the jaundice was directly related to chlordiazepoxide therapy. The temporal coincidence of the beginning of medication and the onset of jaundice is highly sugges-

tive of a causal relationship. There was no evidence of viral hepatitis or liver disease of infectious origin present in the hospital at the time this patient became ill. While the possibility of viral hepatitis must be considered, the likelihood of its presence is uncertain. One cannot rule out the possibility that this patient had an exquisite sensitivity to the combination of diphenylhydantoin, phenobarbital and chlordiazepoxide. It is of interest to note that the onset of jaundice, unaccompanied by subjective symptoms, is in keeping with the usual history obtained in patients suffering from drug-induced icterus.

A CASE OF INHIBITION OF EJACULATION AS A SIDE EFFECT OF MELLARIL

HARBHAJAN SINGH, M.D.¹

INTRODUCTION

It is almost 2 years since Mellaril² has been introduced. The Sandoz Pharmaceutical Company at that time claimed that they had finally found a phenothiazine drug with the same potency as chlorpromazine but with no side effects whatsoever. This drug was accepted, open-heartedly, by practicing psychiatrists and physicians, who previously were quite cautious in their use of phenothiazine due to jaundice, parkinsonism and other side effects. It was soon discovered that, although this new drug was as potent as chlorpromazine, and had fewer side effects, it nevertheless was not virtually free of side effects. The most common symptoms noted were dryness of mouth, a sensation of stuffed up nose and some minor skin reactions. Later some workers reported Retinitis Pigmentosa in certain cases receiving high dosages. Recently we have come across a case demonstrating a rather unusual symptom.

Case Report: A 35-year-old, white, male patient was brought to the Emergency Department of the Ottawa Civic Hospital, Ottawa, Ontario, on September 6th, 1960, in a state of

acute anxiety and stomach distress which had evidently begun several weeks earlier and had been growing progressively more severe. Patient was sitting in a foetal position, unable to move or walk, complaining of pain all over the body and epigastric distress. He claimed he was unable to walk or move because of tension spasms in his arms, legs and neck.

According to the case history, the patient had been nervous and tense all his life, had been drinking excessively for the last 7 years and had been suffering from stomach ulcers for the last 5 years. During the past year, he had also been suffering from dizzy spells and excessive sweating.

The patient was given an intramuscular injection of 7½ gr. of sodium amytal and within half an hour was relaxed and started talking and walking. The patient was then put on Mellaril 100 mgm. t.i.d. and Gelusil (antacid) and was informed that he would be followed up and treated in the outpatient department only if he would guarantee to cease his excessive drinking.

When seen again the following week, the patient was much improved, but was manifesting an unusual symptom. He complained of a complete inhibition of ejaculation during coitus. He had the usual orgasm but there was no discharge associated with it. The patient was reassured, advised to continue with the Mellaril 100 mgm. t.i.d., and asked to return in 2 weeks. When the patient returned, he still

¹ Dept. of Psychiatry, Ottawa Civic Hospital, Ottawa, Gan.

² Thioridazine, Sandoz.

complained of this ejaculatory inhibition. At this time, to ascertain whether this was a side effect of Mellaril, the medication was changed to Stelabid No. 2,⁸ and when the patient returned for his next appointment 2 weeks later, he stated that he had normal ejaculation during

orgasm. Mellaril was again tried for a few days and gave rise to the previous symptom of inhibition of ejaculation.

CONCLUSION

A case is reported showing an unusual side effect due to Mellaril.

⁸ Combination of Darbid and Stelazine, S. K. F.

COMMENTS

EUGENIC STERILIZATION LEGAL IN 28 STATES

The *AMA News* (Jan. 9, 1961) lists the 28 states of the American Union in which laws provide for eugenic sterilization of various classes of persons. According to a staff attorney of the American Medical Association the classes affected include the feeble-minded, the insane, sexual deviates, and habitual criminals.

The states are : Alabama, Arizona, California, Connecticut, Delaware, Georgia, Idaho, Indiana, Iowa, Kansas, Maine, Michigan, Minnesota, Mississippi, Montana, Nebraska, New Hampshire, North Carolina, North Dakota, Oklahoma, Oregon, South Carolina, South Dakota, Utah, Vermont, Virginia, West Virginia, Wisconsin.

The *AMA News* states : "In these states, the physician authorized to perform the operation incurs no personal liability if the operation is performed in accordance with a valid law and without negligence. This holds true even over the objection of the person upon whom he operates."

Ten of the 28 states authorizing eugenic sterilization, namely Arizona, Indiana, Mississippi, New Hampshire, North Carolina, Oklahoma, South Carolina, Utah, Virginia, West Virginia, also provide for therapeutic sterilization; but this does not include sterilization for convenience.

Specifically, in 3 of the 28 states it is held to be a statutory crime to sterilize for other than eugenic or therapeutic purposes. These states are Connecticut, Kansas and Utah.

An A.M.A. staff attorney has pointed out (*AMA News*, Jan. 23, 1961) that : "There are no reported criminal cases involving a physician who performed a sterilization operation solely to suit the convenience of his patient." It may be assumed that no physician would perform a sterilization operation, other than for eugenic sterilization in states where this is authorized without the written agreement of both patient and spouse.

PSYCHE

This is the double conflict, the social opposition and the moral agony, that spirit suffers by being incarnate ; and yet if it were not incarnate it could not be individual, with a situation in space and time, a language and special perspective over nature and history : indeed, if not incarnate, spirit could not *exist* at all or be the inner light and perpetual witness of *life* in its dramatic vicissitudes.

—SANTAYANA

CORRESPONDENCE

THE COMMON FRONTIERS OF PSYCHIATRY AND LAW

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: The authors of the above named article, published in the December 1960 issue, discuss a wide range of topics lending themselves to challenging research. They range from correlation between physical illness and delinquency and factors affecting conformity in legislative policies to processes of struggle in the world community and professional education.

The sophisticated and all-embracing imagination of the authors has, however, one fears, stopped them from seeing the forest for the trees, from facing the stark fact that every year several million appear before the courts in this country, that three million persons are in jail, 1,600,000 for very serious felonies, and that crime constitutes an ever increasingly serious social problem.

Psychiatry should make the social contribution it is capable of, and not be restricted to helping private practice neurotics cope with their minor problems of living, nor concentrate too much on theoretical speculation. While many volumes, psychiatric and sociological, are being published on delinquency, there are only a few psychi-

atrists willing and able to treat serious law-breakers, adult or juvenile. Criminal psychiatry should be taught as a specialty. The failure to treat also handicaps research. How can we study the mentality, background, impact of legal situations, the working of the courts, unless we have sufficiently close contact with them? And how are we to get it unless we treat offenders and cooperate with the courts?

Enlightened courts are only too eager to rehabilitate offenders, but are handicapped by the dearth of constructive facilities. APTO has, since 1950, cooperated most satisfactorily with 17 courts in Greater New York. We are now in the process of setting up an APTO chapter in Washington, D. C., that can provide clinical service, at the request of courts and correctional agencies. Our Massachusetts Chapter, headed by Dr. Donald Russell, comprises 14 court clinics.

There is little doubt that if psychiatrists offered effective service, they would be warmly welcomed by most courts, probation services and correctional agencies all over the country.

Melitta Schmideberg, M.D.,
New York City.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: We congratulate Dr. Schmideberg on her energetic and effective efforts to provide disturbed offenders with treatment. We agree that psychiatric approaches to criminal behavior ought to be taught and that offenders ought to be treated. (The psychiatric author has been doing both for 15 years.)

However, we fail to see any incompatibility between providing criminals with ther-

apy and undertaking investigations designed to study the biologic, psychic, and social factors predisposing to social and behavioral pathology.

Indeed, it would seem self-evident that it is more rational to aim at preventing socially destructive behavior than to concentrate exclusively on treating disturbed individuals after the harmful acts have occurred.

Lawrence Zelic Freedman, M.D., and
Harold D. Lasswell, Ph.D.,
Stanford, Calif.

PSYCHOANALYTIC METHODOLOGY

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: I wonder whether a fundamental error—the incorrect acceptance of the initial response as essentially valid—may exist in psychoanalytic methodology, and whether this error may sometimes tend to undermine human cooperative attitudes and activity in therapeutic practice, in family living and in social theory.

Free association—giving voice to the initial response—is the basis of psychoanalytic and much of psychotherapeutic practice. "Say what comes to mind" is the admonition to the patient. The initial response which then spontaneously occurs is a fundamental part of the "material" upon which the treatment is based. In practice, this initial response tends to be taken as the truest and most accurate expression of the patient's most profound feelings, of his "Unconscious."

But physiology tells us that the initial response of any organism to a stimulus will be based on an exaggeration of its painful qualities, inasmuch as throughout the animal kingdom painful stimuli have priority over pleasurable ones at the moment of stimulation. This physiological consideration would indicate that the initial response would tend to be a distorted one, in which painful elements play a disproportionately large part. In humans, this distortion inevitably present in the initial response is usually corrected by subsequent reflection; for this reason, we are taught to think before

we speak. Unfortunately, however, psychoanalysis does not always seem completely to recognize the existence of the physiologically-determined distortion in the initial response, but instead seems at times to accept this response as valid, accurate and undistorted.

The initial response in psychoanalysis or psychotherapy will, of course, often be about other people or toward them. To the patient, the painful quality of these people will be exaggerated by the distortion inevitable in the initial response. Since interpersonal pain leads to interpersonal hostility, however, acceptance of the exaggerated initial painful quality of the other person as a valid appraisal will tend to cause an overestimation of interpersonal hostility. The tendency toward exaggeration of social conflict and of man's inhumanity to man which might result thereby would seem at least partly responsible for 2 unfortunate consequences: a disruptive effect within the families of some psychoanalyzed people and the pessimism so pervasive today about the possibility of human beings ever getting along harmoniously.

It is then perhaps an artifact of psychoanalytic method, rather than anything scientifically proven, which sometimes leads its supporters to see man's inhumanity and hostility to man as inevitable, both within the family and in society as a whole.

Nathaniel S. Lehrman, M.D.,
Great Neck, N. Y.

RECURRENT PSYCHOTIC DEPRESSION ASSOCIATED WITH HYPERCALCEMIA AND PARATHYROID ADENOMA

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: In volume 117, page 234 of the *American Journal of Psychiatry* Dr. Martin M. Mandel describes, under the heading "Recurrent Psychotic Depression Associated with Hypercalcemia and Parathyroid Adenoma" a case in which at the third recurrence of the depression a calcium determination revealed an elevated calcium level

in the blood serum and a following operation and removal of the parathyroid adenoma brought the patient back to health. In his opinion the symptoms of an adenoma of the parathyroid gland are undistinguishable from those of a depression.

However, psychotic depressions without parathyroid adenoma can be accompanied by an altered blood calcium level. The picture this patient presented would have been

named "agitated depression" according to the old nomenclature. In a paper named "Untersuchungen über den Stoffwechsel bei manischen und depressiven Zustandsbildern. II. Mitteilung: Veränderungen des Kalzium-und Kaliumspiegels des Gesamtblutes," in *Jahrbücher für Psychiatrie und Neurologie*, 1926, Vol. 45, page 32, the writer of this letter has shown that agitated depressions have an elevated calcium level

in the blood. In a monograph titled "Undersøgelser Over Nogle Af Blodets Elektrolyter (Ca, K, Na, H) Og Det Vegetative Nervesystem Særlig Hos Patienter Med Manio-Depressiv Psykose" published in 1927, Helgi Tómasson enlarged and verified my results.

Edith Klemperer, M.D.,
New York, N. Y.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: Thank you for the comment from Dr. Klemperer regarding my recent paper on "Recurrent Psychotic Depression Associated with Hypercalcemia and Parathyroid Adenoma." I state in this paper that the parathyroid adenoma was responsible for producing elevated serum calcium level which I believe to be the cause of this lady's current depressive episode. This has been observed by neurophysiologists who

have found the symptoms of hypercalcemia to be responsible for depression in man as well as in animals. I am also interested in Dr. Klemperer's observation regarding her own personal work with serum calcium and depressions; but in some of my recent research, I have not been able to substantiate her findings of elevated serum calcium levels in patients suffering from involutional psychotic depressions.

Martin M. Mandel, M.D.,
Philadelphia, Pa.

SOCIAL PSYCHIATRY

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: We wish to clarify and correct several points in our review of Social Psychiatry which appeared in the January 1961 issue of the Journal.

1. The sentence appearing on page 613, paragraph 4, should read: "The study of Knobloch and Pasamanick, regarding such variables as *mental deficiency* and seasonal variations in births, has recently been discussed and challenged . . ." The Sterling critique we alluded to referred only to a paper published in 1958, which we inadvertently did not cite in our bibliography. (Knobloch, H., and Pasamanick, B.: Seasonal Variation in the Births of the Mentally Deficient. *Am. J. Publ. Health*, 48: 1201.)

2. The two current publications of Pasamanick *et al.* which we did cite are further epidemiological studies of these investigators which we regard as being of general interest and importance.

3. Yet unpublished at the time of writing of our review was the reply to their critic by Doctors Pasamanick and Knobloch. (Pasamanick, B., and Knobloch, H.: *Am. J. Publ. Health*, 50: 1737, November, 1960.)

4. It has been brought to our attention that the following sentence in our article can be subjected to possible misinterpretation: "Aside from the specific points at issue in this particular controversy is the sobering realization that once results have been published as 'facts' they tend to assume a peculiar life of their own, becoming divorced from the body and context of the investigation from which they derived." Our intent was to paraphrase a general point Sterling makes. We did not wish to cast aspersion on Pasamanick's data, but merely wanted to express that important scientific data need to be corroborated. We neither wished to take sides in the controversy nor to make any invidious inferences. Our position is that only further studies and additional data will serve to clarify the facts. Pending such information, we wish to withhold any judgment. To avoid any misunderstanding, therefore, we are withdrawing the entire sentence.

M. P. Pepper, M.D.,
and F. C. Redlich, M.D.,
Yale University School of Medicine,
New Haven, Conn.

NEWS AND NOTES

FIRST LATIN AMERICAN CONGRESS OF PSYCHIATRY.—This Congress will be held in Caracas, Venezuela, May 28-31, 1961. This Congress has been organized under the sponsorship of the "Asociación Psiquiátrica de la América Latina."

President of the Congress is Dr. Mata de Gregorio of Venezuela, and Vice-Presidents are Dr. Pacheco E. Silva of Brazil and Dr. José Bustamante of Cuba. Other members of the Central Committee are Dr. Risquez Figuera and Dr. Ibañez Petersen of Venezuela.

Dr. Manuel Manrique of New York is the representative in the United States and Canada.

The official agenda will include: 1. Psychiatric care in Latin America; 2. Teaching of psychiatry in Latin America; 3. Discussion of modern research on epilepsy.

DR. FREYHAN GOES TO N.I.M.H.—Dr. Fritz A. Freyhan, assistant professor at the University of Pennsylvania and director of research at Delaware State Hospital has been appointed Clinical Professor of Psychiatry at the George Washington University and Deputy Chief of the Clinical Neuropharmacology Research Center in Charge of Clinical Studies at the National Institute of Mental Health, Bethesda, Md. The Research Center is a joint research facility of the N.I.M.H. and St. Elizabeths Hospital in Washington. The Center, which is physically located at St. Elizabeths Hospital, is under the immediate direction of Dr. Joel Elkes, Chairman of the joint committee on research, NIMH-SEH.

Dr. Freyhan, born in Germany, has been an American citizen since 1943. He has been associated with Delaware State Hospital, Farnhurst, Delaware, from 1940 until assuming his present duties at the Clinical Neuropharmacology Research Center, February 15, 1961.

CERTIFICATION OF PROFESSIONAL SOCIAL WORKERS.—A nationwide plan for the certification of professional social workers will be

put into effect on Dec. 1, 1961 by the National Association of Social Workers. Those social workers who apply for and obtain accreditation by an Academy of Certified Social Workers will be permitted to use the initials "aCSW" in signing their names and to display in their offices an annually renewable certificate.

At present more than 25,000 current full members of NASW will receive applications for membership in the Academy. Full members of NASW on Dec. 1 may be certified on that date if they have been members of the Association for two years of paid social work employment. Other full members on that date have two years to meet these conditions. Social workers entering NASW after Dec. 1 will have to meet more extensive requirements, including two years employment in one agency under supervision of a certified social worker.

NATIONAL INSTITUTES OF HEALTH GRANTS FOR STUDY OF AGING.—The NIH has made 64 grants to private institutions totaling \$1,427,883 for research in various aspects of aging. These grants have been made to investigators in 25 states and the District of Columbia, with one for studies at the University of Cape Town, South Africa.

Twenty-three grants, amounting to \$389,729, are continuations of previous projects, while 41, totaling \$1,038,154, are new grants. One new award by the Division of General Medical Sciences to Brown University, Providence, R. I., provides for the establishment for a university-wide center to study the socio-economic factors and to assess their relationship to the medical and biologic aspects of aging. Other institutions with similar grants are: Duke University, Albert Einstein College of Medicine, Western Reserve University, and the University of Miami School of Medicine.

The NIH is supporting 700 research projects related to aging at a total annual expenditure of \$16,234,564. These figures are for a one-year period ending Jan. 31, 1961.

THE NEW YORK STATE INSTITUTE FOR RESEARCH IN MENTAL DEFICIENCY.—Governor Rockefeller has announced that a new Institute for basic research in mental retardation, believed to be the first of its kind in the world, will be established adjacent to the Willowbrook State School on Staten Island on land already owned by New York State.

The Institute will be an independent facility with its own director and staff. It will comprise laboratories, clinical facilities, and administrative offices. Individual laboratories will provide for studies in psychology, biochemistry, pharmacology, genetics, and microbiology, biophysics, metabolism and pathology. There will also be facilities for animal studies.

Proximity to Willowbrook State School will provide a broad range of cases for study. The clinical areas of the Institute will contain several small wards constructed to permit continuous observation and recording of patients' behaviour.

DR. IRVING HYMAN.—Dr. Hyman, 52, professor and chairman of the department of neurology at the University of Buffalo Medical School and chief of neurology at Buffalo General Hospital, died March 7, 1961 in Roswell Park Memorial Institute.

In 1929, Dr. Hyman received his B.A. and his M.D. from the University of Buffalo and did postgraduate work in neuropathology at Maudsley Hospital, England. He is a diplomate of the American Board of Psychiatry and Neurology.

He entered the Medical Corps in 1942 as a major, serving as head of the neuro-psychiatric division of the 23rd General Hospital at Ft. Meade, Naples and Vittel. Two years ago he became chief of neurology at Buffalo General Hospital.

Being active in many professional and community organizations, Dr. Hyman was a member of the Executive Committee of the Medical School and director of electroencephalography at both General and Milard Fillmore Hospitals.

1961 WORKSHOP IN THE RORSCHACH TECHNIQUE.—This workshop, jointly sponsored by Claremont Graduate School in Claremont

and Childrens Hospital; Los Angeles, will be held September 3 to 15 at Acilomar Conference Grounds, Pacific Grove, Calif. It will be devoted to the study of projective techniques as used with children; a number of courses will be available.

Tuition is \$50.00. For applications write to Dr. Bruno Klopfer, P.O. Box 2971, Carmel, Calif. before Aug. 1. Qualified graduates accepted for the workshop may apply for 2 units of credit (Psychology 243, or 244a,b,c) to the Claremont Graduate School, Claremont, Calif. before Aug. 1.

INSTITUT ALBERT-PREVOST ACCREDITED.—The Institut Albert-Prévost of Montreal, Canada, has recently been fully approved by the Central Inspection Board.

At the present time, only 76 hospitals have been given full accreditation by the American Psychiatric Association, a distinction held by only 2 other psychiatric hospitals in Canada. This approval was granted following a comprehensive survey and a rating of the hospital based on standards formulated by the Committee on Standards and Policies of hospitals and clinics.

The Institution is affiliated with the University of Montreal, Department of Psychiatry, for under and postgraduate training of residents, psychologists, social workers and psychiatric nurses.

AMERICAN PSYCHOLOGICAL ASSOCIATION.—The 69th Annual Convention of the American Psychological Association will be held at the Commodore, Biltmore and Roosevelt Hotels in New York City, August 31-September 6, 1961.

Members and guests will not only attend meetings and read papers, but will also visit the many exhibits provided to catch up on recent developments in instrumentation, tests, books and other publications, etc.

For regulations and forms for the 1961 Convention write to: Mr. George S. Speer, Institute for Psychological Services, Illinois Institute of Technology, 3329 S. Federal St., Chicago 16, Ill.

APPOINTMENT OF DR. RICHARD L. JENKINS AS PROFESSOR OF CHILD PSYCHIATRY.—This appointment to the Department of Psychia-

try at the University of Iowa has been announced. Dr. Jenkins had previously been with the Veterans' Administration as Director of the Psychiatric Evaluation Project. Prior to this he worked in child psychiatry. After serving as Pediatrician at the Institute for Juvenile Research Dr. Jenkins studied with Dr. Adolf Meyer as a Rockefeller Fellow. He served as psychiatrist at the New York State Training School for Boys at Warwick and at the Michigan Child Guidance Institute in Ann Arbor. He returned to the Institute for Juvenile Research, first as chief psychiatrist, then as acting director. Following this, he was psychiatrist in the Health Service of the University of Illinois at Urbana.

DR. HAMBURG TO HEAD PSYCHIATRY AT STANFORD.—Dr. David A. Hamburg, chief of the Adult Psychiatry Branch of the National Institute of Mental Health in Bethesda, Md., has been appointed professor and executive head of the department of psychiatry of the Stanford University School of Medicine. He will assume his new duties Aug. 1, 1961.

With the appointment of the new dean, Dr. Robert H. Alway in 1952, a reorganization plan was adopted to make the medical school an integral part of the University. To this end six heads have been appointed, Dr. Hamburg being the last.

ALFRED KORZYBSKI MEMORIAL MEETING.

—This annual Memorial Meeting took place on the evening of Apr. 20, at the Harvard Club in New York City. Robert R. Blake, professor of psychology at the University of Texas, and organizational consultant, spoke on "From Industrial Warfare to Collaboration: A Behavioral Science Approach."

THE NEW YORK ACADEMY OF SCIENCES.

A conference on "Fundamentals of Psychology: The Psychology of the Self" will be held under the auspices of this Academy at the Barbizon-Plaza Hotel in New York City on May 11 and 12, 1961.

An invitation to attend the conference will be issued to interested professional persons upon request. There is no registration or other obligation of fee for those attend-

ing. Such requests should be addressed to The Executive Director, The New York Academy of Sciences, 2 East 63rd Street, New York 21, N.Y.

DR. PASAMANICK HONORED.—Dr. Benjamin Pasamanick, Professor of Psychiatry at Ohio State University and Director of Research at the Columbus Psychiatric Institute, received the \$500 Stratton Award of the American Psychopathological Association for 1961 for his studies on the epidemiology of mental disorder. Dr. Pasamanick has received the two major awards for research in psychiatry given by national organizations, having been awarded the Hofheimer Prize of the American Psychiatric Association in 1949 for his studies on child development.

INSTITUTIONALIZING YOUNG DEFECTIVES.

An experimental program to provide comprehensive community care for retarded infants and their families was initiated at the New York Medical College, Flower and Fifth Avenue Hospitals, New York City, by the New York State Department of Mental Hygiene on March 1, 1961. The purpose is to determine whether such service can reduce the need for institutionalization of the young retarded.

The two-year project will be financed by a \$60,000 yearly grant from the Department of Mental Hygiene. Mongoloid retardates under 5 years of age from the New York City area will be selected from existing department waiting lists for the study.

Deputy Commissioner Pense reports that the number of applications for admission of children under 5 has increased steadily in recent years; approximately 40 applications are filed monthly in the New York City area. It is hoped that if parents are given appropriate advice as well as emotional support through psychiatric and social work methods, many of these children could be cared for at home for a number of years.

PSYCHIATRIC AND NEUROLOGICAL CONGRESS IN THE FRENCH LANGUAGE.

—This Congress will hold its 59th session at Montpellier, July 10-15, 1961. At the psychiatric section Messrs. Warot and Fossati (Lille)

will discuss the endocrine psychoses.

In the neurological section Messrs. Pellegrin and Darcourt (Marseille-Nice) will report on the occipital lobe in the light of new neurosurgical and neurophysiological findings.

Representing the forensic section Monsieur J. Ley (Bruxelles) will speak on the medico-psychological and social bases of the criminal law.

Dr. Paul Cossa, 29 Boulevard Victor-Hugo, Nice, is the Secretary General of this Congress.

RESEARCH PROJECT ON HABIT FORMATION AND DRUG ADDICTION.—The new *Monograph Series on Child Psychiatry*, published by Pergamon Press, plans a volume on habit formation related to foods and medicines and drug addiction in youth from infancy to age 20. Reports on individual cases and any kind of experiences with such pathology will be welcomed. All material should be sent to the editor, Dr. Ernest Harms, 158 East 95th Street, New York, N. Y.

CONFERENCE ON DREAMS.—On May 24, 1961, 8:30 p.m. at the New York Academy of Medicine, the Association for the Ad-

vancement of Psychoanalysis will hold a meeting devoted to "The Dream—A Mobilizing Force in Therapy." The principle speaker will be Dr. Frederick A. Weiss, whose concepts of dream interpretation embrace the contributions of all analytic schools. The discussants are Dr. Harry Gershman and Dr. Edward S. Tauber (by invitation).

PSYCHODRAMA AND GROUP PSYCHOTHERAPY.—The American Academy of Psychodrama and Group Psychotherapy will hold a one-day meeting at the Morrison Hotel, Chicago, Ill., on Sunday, May 7, 1961. Participants may write to Dr. Robert S. Drews (M.A.P.A.), President, 12500 Broadstreet Blvd., Detroit 4, Mich.

PROFESSOR FRANKL COMES TO HARVARD.—Dr. Viktor E. Frankl, Professor of Psychiatry at the University of Vienna and head of the Neurological Department of the Vienna Poliklinik, comes to Harvard University for the summer session, June 26 to August 18, 1961. He will offer the Course S182—The Abnormal Personality, 9-10:00 A.M., Monday through Friday; and Seminar: Existence and Values: Foundations of Logotherapy, Tuesday and Thursday, 2-4:00 P.M.

PRESENTING PAPERS

In my opinion the reading aloud of a written paper is a cardinal sin, as deplorable as meretricious writing; it is a wicked procedure, utterly contemptuous of the audience and unfair to it.

—GEORGE SARTON
Historian of Science

EXPERIENCE

We learn from experience that men never learn anything from experience.

—C. B. SHAW

BOOK REVIEWS

AMERICAN HANDBOOK OF PSYCHIATRY. Edited by *Silvano Arieti*. Editorial Board: *Kenneth E. Appel, David Blain, Norman Cameron, Kurt Goldstein, Lawrence C. Kolb*. (New York: Basic Books, Inc. 1959. Volume One, pp. 999, Volume Two, pp. 1099.)

The editor has done a remarkable job in record time. There are more than 2,000 pages in 100 chapters and 15 main parts reaching from a pedestrian first historical chapter over Zen Buddhism and Martin Buber to Mental Hygiene and psychiatric organizations in the U.S.A. There is first a general part with an admirably concise and solid chapter on genetics by Kallman, a part on psychoneuroses and the like, a part on the functional psychoses most of which is covered by Arieti quite satisfactorily. Part Four contains Psychopathies and Addictions, Part Five, Psychosomatic Medicine; here is an interesting report on disturbances of the body image by L. C. Kolb. Parts Six and Seven deal with Childhood and Adolescence and with Language, Speech, and Communications, respectively. Part Eight, Organic Conditions, is the beginning of Volume Two. In the first chapter on neurosyphilitic conditions, W. L. Bruetsch has done very well. There are useful contributions on Postencephalitic Conditions by Hans Strauss and on Psychoses with Huntington's Disease by Bigelow, Roizin, and Kaufman.

Part Nine brings the psychotherapies, Part Ten the Psychoanalytic Therapies. In Part Eleven the great experience of Kalinowsky on Convulsive Shock, of Freeman on Psychosurgery and of Hoch on Drug Therapy are welcome and unusually helpful. In Part Twelve, among other topics, Neurophysiology is done by Gerard, Neurology by Cobb—it is not possible to mention everything and everybody.

Part Thirteen has a touch of Philosophy, Religion, and, as mentioned, Zen Buddhism and Buber. The last two chapters are dedicated to management and care of the patient and to legal, administrative, didactical, and preventive psychiatry.

This is quite a *tour de force*—is it not? It is obvious that not all the chapters can be equally good. At any rate, this *Handbook* may be used advantageously by the experienced psychiatrist; it ought not to be recommended to the beginner.

The historian (Nolan Lewis) opines that since 1937 an American School developed in

Psychiatry. No use to argue about this claim as one would have to define "school" first. That the attitude of the American Psychiatrist is fundamentally pragmatic is not news—not bad news, anyway. For this reviewer, the nosological kinship to Kraepelin's system is impressive in this work. It is, for this reviewer, no less impressive that, if he is counting correctly, of 111 contributors there were 96 physicians, *i.e.*, doctors of medicine. A considerable number of the contributors got their training abroad. Arieti is a graduate of the University of Pisa (Italy) Medical School.

Arieti has made some very short and clear remarks on the Existentialist School (pp. 423-424) for which he merits a special compliment.

The chapter "The Existential Approach" is written by Rollo May, a psychologist, who, in this reviewer's opinion, has an unfortunate love affair with the pertinent philosophy.

EUGEN KAHN, M.D.,
Houston, Tex.

CURRENT THERAPY, 1960. Edited by *Howard F. Conn, M.D.* (Philadelphia: W. B. Saunders, 1960, pp. 808. \$12.00.)

This is the 1960 edition of a well-known annual series which deals in a practical way with methods of treatment of a wide variety of diseases. In each case one of the contributors describes his own methods of treating this particular disease. Since there are over 300 contributors to this edition, there is a good deal of variation in the style and the approach to the subject. However, the contributors are generally of a high calibre, and in the majority of cases they present useful and up-to-date information on methods of treatment, the most effective drugs with details of their dosage and administration, toxic or side effects of the drugs, and the expected response of the patient. Since it is one man's method of treatment that is presented, there is usually no attempt made to discuss the pros and cons of all the current methods of treatment for a disease, but rather the ones that the contributor has found most effective in his own practice.

The section on psychotherapy is written by V. Gerard Ryan of Portland, Conn. It is intended to guide the general practitioner or internist in the treatment of patients with neuroses and psychosomatic illnesses. There is a brief discussion of psychotherapeutic techniques, drug therapy for symptomatic relief, and the selec-

tion of patients who should be referred to a psychiatrist for consultation or treatment. Obviously it is difficult to cover such a broad field in a few pages, but there is a good deal of practical information that should be helpful to most physicians.

The psychoses are considered under the headings of schizophrenia, mental depression, manic-depressive disease and delirium. Here is discussed the role of the general practitioner in the treatment of psychoses, the management of acutely disturbed patients. There is a brief outline of some of the current methods of treatment of mentally ill patients in hospital and drug therapy. Indications for electric shock therapy are covered.

Included in the appendices are a roster of drugs giving common trade names and dosage, a table of pediatric dosages, normal laboratory values, and poisonous substances in many household and commercial products. There is a good section on acute poisoning. Generally this is a very useful reference book for a physician in almost any branch of medicine.

A. D. McKELVEY, M.D.,
University of Toronto.

RESEARCH CONFERENCE ON THERAPEUTIC COMMUNITY. Compiled and edited by *Herman C. B. Denber*. (Springfield, Ill. : Charles C Thomas, 1960, pp. 265. \$11.00.)

This book is a series of 14 papers which were presented at a research conference held in the Manhattan State Hospital, March 13-15, 1959, under the chairmanship of Henry Brill. This same group had held a previous meeting in Montreal and the proceedings of that meeting are chronicled in *The Dynamics of Psychiatric Drug Therapy* (ed., G. J. Sarwer-Foner, Springfield, Illinois, Charles C Thomas).

A variety of aspects of the therapeutic community are covered in the various papers and if there is any central theme it may be the emphasis upon conversion of the milieu to a greater degree of "therapeuticity" than existed before. H. Brill in his opening remarks reviews the history of the therapeutic community under its various aliases, emphasizes that this is not something new and warns that humanitarian improvements are reversible.

Chittick, Brooks and Deane describe and discuss the 8-point Vermont State Hospital program, and the excellent results that ensued. At the completion of this program the discharge rate almost approximated the admission rate.

Irvin discusses modification of social behavior of animals through the use of drugs.

He concerns himself exclusively with sub-human social organizations where it has been demonstrated that drugs may alter competitiveness, cooperativeness, locomotor activity, aggressiveness, sexual behavior, apprehension and anxiety, imprinting, resistance and contagious behavior. All are factors relevant to the type of social organization that is operating. He prudently refrains from any sweeping generalizations as to how this information may have application to our concepts of human social organization although he suggests that this information is relevant.

Meszaros discusses principles of research in a therapeutic community setting and points out advantages and disadvantages. His primary contention seems to be that in those instances where the research process conflicts with the therapeutic goals, it must adapt its methods and objectives to become compatible with the treatment milieu.

Denber presents a paper which is primarily a documentation of the transformation of a state hospital ward of chronically ill female psychotics from a custodial to a therapeutic regime (over a 2 year period). His paper best exemplifies the important principles of the therapeutic community, although some of the other papers stressed some of these principles as well.

Denber pin-points and high-lights the following factors: 1. The crucial relationship between administration and staff, 2. The importance of staff attitude—especially their preparation for change and the value of their cooperation, 3. The importance of recognizing the dignity of the individual—both patient and personnel, 4. The need for mutual respect between the psychiatric disciplines and 5. The ever present conflict between custody and therapy.

Sarner-Foner, Ogle and Dancy document a similar effort at Ste. Anne's Hospital in Montreal. Their paper contains greater detail of the physical organization of the ward and in many respects repeats the principles discussed by Denber. This paper is particularly valuable for one who is planning his first conversion to a therapeutic regime. It contains much practical information.

Greenblatt and Levinson document the results of some of their open door experiments. This is covered from the viewpoint of each of the psychiatric disciplines involved—and the difficulties encountered before success was attained. They conclude, after two years of effort, that "the open door is a fait accompli. It is accepted. It is good." At the same time though they stress that "taking the United States as a whole, the overwhelming majority

of hospitals are not open at all." They conclude with "an open door without an open mind is bound to be a failure."

Roberts reports upon his experiences in implementing the therapeutic community by means of group meetings. In his opinion it has proven to be a valuable tool. He makes a sharp distinction between group meetings and group therapy. Gralnick emphasizes the relationship between psychiatrist, patient and family and stresses that "total" treatment involves participation of each member of this triad. Boad discusses the day hospital as a therapeutic community and points out the need for this specialized facility, its advantages and pitfalls.

Kwalwasser documents the development of an adolescent pavilion for girls at the Hillside Hospital, some of the difficulties encountered and how they were overcome. This unit, during its development, felt a need to be more closely identified with the total hospital but was thwarted in this aspiration. He concludes that "the higher the esprit de corps in the unit, the great stress and strain it can successfully and therapeutically absorb."

Klerman discusses factors and attitudes which are involved in the arrival at a decision to use drug therapy. He clearly brings out personal and social factors which seem to be relevant although some psychotherapists might take issue with some of his conclusions. "Staff attitude to a particular form of treatment and the choice of treatment for a particular patient might be the condensed expression of the interpersonal forces which surround the patient in the hospital milieu."

Bullard and Hoffman studied the factors which influenced the discharge of a group of chronic, schizophrenic patients. In those patients in whom discharge became a reality, they found that the significant factors were (a) good hospital adjustment, (b) psychotherapeutic relationship with a doctor or social worker, (c) satisfactory attitude of the patient's family and (d) availability of adequate community resources.

E. B. Kris discusses factors which facilitate and prolong patients' release from the hospital. She stresses (a) individualized attention and (b) the need to become self-supporting.

This book is a documentation of some of the, as yet, all too few attempts to convert to a therapeutic or open door regime. The majority of the papers agree to a remarkable extent about which factors are relevant. Almost all of the papers emphasize the importance of the social processes involved. The volume is written in a simple and factual manner and there

is a minimum of dynamic interpretation. Most of the reports are almost a narrative description and they will be invaluable to anyone contemplating the introduction of an open door policy.

PAUL E. FELDMAN, M.D.,
Topeka, Kansas.

LAW AND MEDICINE. By William J. Curran.
(Boston: Little, Brown & Co., 1960, pp. 829. \$12.50.)

The preface to this book commences, "This volume is presented as a text and casebook for practicing attorneys and students of law in those areas of medical science, medical practice, and public health which are most significant to law, our legal system, and the practice of law in the United States today."

In view of this statement, it might be thought that *Law and Medicine* would be of little interest to psychiatrists. The contents lead to a different conclusion. There is a long chapter, comprising 124 pages, devoted to psychiatry and law. The author states, "This is the only chapter in this volume devoted to a single aspect of medical science. There are so many areas of the law, in its theoretical foundations as well as its practical aspects, where psychiatry is vitally involved that it seemed to warrant such treatment."

The topic has been explored thoroughly, including such aspects as psychopathic personality, criminal responsibility, sex offenders, testamentary capacity and domestic relations.

Anyone who is interested in forensic psychiatry will profit by reading Professor Curran's book.

HERITABLE DISORDERS OF CONNECTIVE TISSUE. 2nd Ed. By Victor A. McKusick. (St. Louis: C. V. Mosby Co., 1960, pp. 333.)

A welcome second edition of a most informative work on the clinical and genetic facts relating to the disorders of connective tissue. McKusick seems to have covered everything on the subject, and his bibliographies are invaluable. What is remarkable is the frequency with which these hereditary disorders involve a mental deficit. This is a matter which McKusick does not discuss. "The connective tissue disorders are readily understandable on the basis of a genetic defect involving mesodermal tissues, but in the cases with accompanying mental defect it is difficult to account for the condition. There may or may not be an ectodermal defect. Much more likely is the possi-

bility of an enzymatic defect. But this is conjecture and what is called for is investigation. The present volume performs the dual valuable functioning of providing all the available information relating to these disorders, and the direction in which further work requires to be done. That work, I suspect, will be largely biochemical in nature.

PSYCHIATRIC SERVICES AND ARCHITECTURE. By A. Baker, R. L. Davies, and P. Svadon.^o (WHO Public Health Papers, No. 1, 1959, pp. 58, 60c.)

This paper is a follow-up on the 1952 report of the WHO Expert Committee on Mental Health which set out the principles which should govern the structure and functions of psychiatric hospitals. It was prepared by the Physician-Superintendents of two mental hospitals (one in Britain, one in France), and by the Director of the Division for Architectural Studies of the Nuffield Foundation. In drawing up the text these eminently competent men consulted "twenty-nine psychiatrists from thirteen countries and from architects from three countries." The resulting report follows the same general principles of previous reports advocating facilities for community care, small hospitals close to centres of population, etc. However, it is not old stuff. Its freshness is due to its style which is succinct, coherent and clear, while in content it presents a comprehensive statement on psychiatric services, with sufficient detail to clearly relate specific architectural arrangements to patient needs.

Since this report is brief considering its scope, since it is easy to read, and since it sounds eminently sensible, it should be read at first hand rather than through a reviewer, particularly since it is in contrast with much that is still being done in hospital planning and design.

CLINICAL MANAGEMENT OF BEHAVIOR DISORDERS IN CHILDREN. 2ND ED. By Harry Bakwin and Ruth Morris Bakwin. (Philadelphia: W. B. Saunders Co., 1960, pp. 597.)

This admirable work has established itself as a standard work on the diagnosis and management of behavior disorders in children. Written with balance and clarity by a husband-and-wife team of pediatricians of long

and great experience it is a pleasure to welcome the second edition. The book is designed to appeal to a wide range of workers, psychiatrists, pediatricians, general practitioners, psychologists, social workers, and whoever else may in any way be concerned with understanding and treating healthy as well as problem children.

References following each chapter are judiciously chosen, and form a most valuable feature of the book, and there are excellent author and subject indices.

THE CENTRAL NERVOUS SYSTEM AND BEHAVIOUR. Selected Translations from the Russian Medical Literature under the joint sponsorship of the Josiah Macy, Jr. Foundation and the National Science Foundation. (Bethesda, Md.: 1960.)

This volume of 1051 pages was prepared for distribution by the Russian Scientific Translation Program, National Institutes of Health, Bethesda, Md., primarily for distribution to medical libraries throughout the United States and Canada.

In his preface to the volume Frank Fremont-Smith, M.D., Director of the Josiah Macy, Jr. Foundation states that "the articles selected do not necessarily represent the best research conducted in Soviet laboratories, but were selected as being generally representative of some of the more recent Soviet research concerned with the understanding of human behaviour." Many of the articles are unlikely to be available to individuals who do not read the Russian Language.

C.B.F.

MENTAL DISEASE AMONG JEWS IN NEW YORK STATE. By Benjamin Malzberg, Ph.D. (New York: Intercontinental Medical Book Corporation, 1960, pp. 140. \$3.75.)

The search for etiological clues is one of the major functions of statistical analysis in medicine. This book presents the findings of Dr. Malzberg's investigations into the truth about the incidence of mental disorders among Jews: to those who have followed Dr. Malzberg's valuable contributions to our available knowledge on mental disorders, it will be of special interest.

This study presents statistics on the incidence of mental disease among Jews and white non-Jews in New York State and New York City, based on first admissions to all mental hospitals in New York State during the fiscal

years 1931-1941 inclusive. The distinctive pattern of Jewish experience in mental disorders—a higher relative and absolute incidence of the psychoneuroses and the functional psychoses, and a lower incidence of the organic psychoses—is noteworthy.

Eight groups of mental disorders in two categories, psychoses of organic origin and functional disorders, were studied. The organic group comprised 27.2% of total Jewish first admissions and the functional group 59.8%; the organic group comprised 42.9% of non-Jewish white first admissions, the functional group 40.8%. The observed crude first admission rates per 100,000 population for New York State are as follows:

Diagnosis Category	Jews	Non-Jews (white)
Psychosis with cerebral arteriosclerosis	17.1	20.6
Senile psychoses	8.0	12.6
General paresis	3.0	6.4
Alcoholic psychoses	0.6	8.3
Total organic group	28.7	47.9
Schizophrenic disorders	32.5	24.9
Manic depressive psychoses	12.9	7.9
Involuntional psychoses	9.4	7.1
Psychoneuroses	8.3	5.4
Total functional group	63.1	45.3
All mental disorders	105.6	111.1

As the author points out, while "there may be some dispute as to the validity of first admissions as a complete measure of the incidence of mental diseases . . . their superiority over any other measure now available cannot be denied. . . . We shall leave to the future, attempts to unravel the social and psychological factors that may be basic to the question of differences in mental disease between Jews and any other ethnic group. In the light of the evidence in this study, it must be concluded that the differences are not in the quantitative direction that has been implied in the past, but rather along qualitative lines that require further investigation."

This study is a lesson in the utilization of available mental health statistics. It provides valuable descriptive epidemiological information and should serve as a stimulus to others to pursue further work in this area.

DELINQUENCY AND PARENTAL PATHOLOGY. By Robert S. Andry. (London: Methuen & Co. Ltd., 1960, pp. 170. \$3.00.)

The author of this book has set up an experimental design directed towards examining

the emotional triangle between child, mother and father.

The basic technic utilised is an interview-questionnaire. The author sets up a series of hypotheses concerning child-parent relationships and attitudes. These hypotheses are tested by analysing the data obtained through the interview-questionnaire.

The experimental group consisted of 80 boys adjudged to be delinquent and the control group of 80 non-delinquents carefully matched, as regards recognised variables, with the experimental group. The technic aimed at not only obtaining data as the child sees the parent role, but also assessing how each parent sees the role he or she plays with the child.

The analysis of the data substantiates the importance of maternal deprivation as an etiological factor in social mal-adjustment. It also clearly indicates that the paternal role is of equal or greater importance as an etiological agent in delinquency.

Dr. Andry has made use of an interesting method of gathering data, concerning parent and child attitudes towards each other. In my opinion this is an important contribution in understanding delinquency, and it indicates the need to carefully study both the child's perception and the parents' perception of their individual roles.

The author provides an appendix to his work titled "A Review of the Literature," which refers briefly to many of the major works of research related to juvenile delinquency. It is, however, far from complete and contributes only in a limited fashion to the usefulness of this book.

The book may be considered as a useful description of a research method and a helpful analysis of certain data related to parental and child attitudes. In my opinion the book would be primarily useful for those engaged in research related to Juvenile Delinquency.

Thistletown Hospital, Ont.

REFLEXES TO INTELLIGENCE. By Samuel J. Beck and Herman B. Molish. (Glencoe, Ill.: Free Press, pp. 669, 1960. \$8.50.)

Here two experienced clinical psychologists have assembled no less than 73 selections from the literature of clinical psychology illustrating the evolution of this large and growing field. But this is far more than just another reader. Each chapter is preceded by an introduction, commenting upon the significance of the authors and their viewpoints, and followed by a list of auxiliary readings, many of these accompanied with a brief comment.

Pointing out that the "first man was very likely the first psychologist," the authors devote Section 1 to Clinical Wisdom in Former Times (Homer, the Bible, Shakespeare). Sources and Foundations (Sec. 2) reproduces articles by Darwin, Titchener, Sherrington, James and Dewey, among others. In The Quest for the Whole Person (Sec. 3) we find Freud, Jung, Adler, Sullivan and Cobb. Section 4, The Measure of the Mind, deals especially with psychometrics—Binet, Terman, Wells, Wechsler, and Lightner Witmer (whom he credits with probably having originated the term "clinical psychology").

Disciplines in Interaction (Sec. 5) records the "maturation of clinical psychology"—the cross fertilization of social work, psychology and psychiatry. Due credit is given to Healy as one of the fathers of clinical psychology and to the late Lawson Lowrey, to whom the book is dedicated. Some others quoted in this chapter are Kasanin, Grinker, Kretschmer, Sheldon and Doll.

Next comes a Section (No. 6) on Humans in their Social Context, with selections by Wells, Woodworth and Beck. In the latter selection the author emphasizes the relations of clinical psychology, based on science and humanism, to the demands of other disciplines, especially the social ones. The entire selection is most thoughtful and illuminating.

Finally, in a Section (No. 7) entitled Today's Theorists—Tomorrow's Realists? we find articles by such authors as Burt, Lewin, Rapaport, Rogers, Rorschach and v. Bertalanffy.

The reviewer is tempted to cite many quotations from the introductions to the various sections as well as from the selections themselves, but space hardly permits.

A final quotation from the authors' introduction to the concluding section must suffice: "So from Darwin to von Bertalanffy we have reached full circle—In between these two writers—are the samplings from numerous others in the intervening 100 years.—They embrace that range which Spinoza envisioned of man in his smallness and in his potential greatness." (p. 511)

Saint Elizabeths Hospital,
Washington, D. C.

ATLAS OF NEUROSURGICAL TECHNIQUES. By James L. Poppen, M.D. (Philadelphia and London: W. B. Saunders, pp. 522, ill., 1960. \$28.00.)

The purpose of this Atlas is to illustrate and describe in orderly sequence the techniques of neurosurgical procedures. The drawings, done by several artists, are excellent, and accurately focus the factors that the author considers important and to which he draws attention with a few short statements. In general when the Atlas is opened, the right hand page is filled with several drawings, with the essential anatomical and pathological structures clearly labelled. On the opposite page a few short sentences refer in some further detail to the drawings. In this way the orderly and planned steps of all the neurosurgical procedures that this reviewer can think of have been covered.

When referring to some particular problem with which the reviewer is familiar and has had some experience it is disappointing to find little said about the technical difficulties, and complications. It is these things that develop over the years that makes surgical wisdom and judgement so difficult to pass on and to put in writing.

The Atlas will be of great value to all neurosurgeons. Variations from the reader's personal technique can be quickly and easily appreciated. Even the very experienced neurosurgeon will pick up valuable points, knowing full well that the author has been through the mill and has had a vast experience in the encyclopedic range of neurosurgical procedures covered in this superbly illustrated Atlas.

In 1922, the reviewer first saw Doctor Lahey operate. The general impression was one of perfection in all operating room details. The personnel functioned at its best individually and as a team and all were under the certain direction of a great master general surgeon. Much of this rubbed off on one of his favorite pupils, Jim Poppen, constituting a base on which to develop his own superb technique and the ability and knowledge to enable him to publish this very excellent and valuable *Atlas of Neurosurgical Techniques*. It is a pleasure and a thrill to review a book when one has known and admired the author for a great many years.

Toronto General Hospital.

PROCESSES OF "SPONTANEOUS" RECOVERY FROM
THE PSYCHONEUROSES¹IAN STEVENSON, M.D.²

INTRODUCTION

Experiences useful in learning new behavior may occur with or without other persons. If they occur with other persons, these may or may not be formal psychotherapists. When patients recover by themselves or with the help of persons other than trained psychotherapists we consider their recoveries "spontaneous."

Reports of instances of spontaneous recoveries from the psychoneuroses have appeared from time to time in the literature of psychiatry and psychoanalysis (1, 2). References to the subject in psychoanalytic writings sometimes leave the impression that such recoveries occur rarely and that when they do, the recoveries are usually insubstantial or transient (3). Recently several independent studies of untreated patients with psychoneurosis have shown that between 40 and 60% of such patients recover within a few years of the first observations of their conditions (4, 5, 6, 7). In these studies, the investigators applied criteria of recovery used for patients who have received psychotherapy and this leaves no grounds for supposing that the spontaneous recoveries were spurious or any less stable than those brought about by treatment. Apparently the patients who recovered spontaneously had experiences in their life situations which permitted them to unlearn maladaptive behavior and learn new, more adaptive behavior.

Several therapists have reported series of patients treated by methods which make deliberate use of the patient's opportunities for learning with persons other than the therapist (8, 9, 10). The results with these methods seem fully as good as those with psychotherapies that emphasize the patient's

experiences with the therapist. Moreover, the results were achieved in a much smaller number of therapeutic hours, presumably because "practice" between therapeutic sessions reduced the time needed for instruction just as it does in learning to dance, ski, or speak a foreign language. We cannot make final judgments of the merits of different therapies without careful comparisons of matched groups of patients treated by different methods. The comparisons mentioned, however, justify careful studies of the processes of spontaneous recovery. From investigations of such recoveries we may learn new ways of facilitating recovery from the psychoneuroses in those patients who come to us for treatment.

For some years I have collected accounts of spontaneous recovery from mental illnesses or improvements in them. I have gathered these from a number of places, including patients, friends, and various published sources.³

In considering changes brought by life experiences, I refer to changes in habitual behavior and attitudes, and not to changes only in feeling states. Thus the pleasant glow which might follow hearing that one had inherited a fortune is a change of feeling, not of values nor of behavioral responses; I believe that a person changes his personality only when the inheritance of a fortune comes to mean less (or more) to him than it did previously, *i.e.*, when the same outward event produces in him a different response.

In making the distinction between changes in feelings only and in behavioral responses, I do not mean to say that a favorable turn in the patient's life situation can only bring a change in feelings. Many of the cases I have collected show the value of changes

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Department of Neurology and Psychiatry, University of Virginia School of Medicine, Charlottesville, Va.

³ I am grateful to Drs. Jacob Weisler and S. A. Steiner for permission to mention cases observed by them and to Dr. Joseph Wolpe for helpful suggestions about the organization of case material and interpretations of the cases.

in a patient's life which provide him with opportunities for learning new behavioral responses. For example, Abraham reported a complete reform in a man who had been all his life a cheat and impostor. The transformation of this patient occurred after his marriage to an elderly widow who satisfied his needs for affection and attention which he had previously only gained by dishonesty(1). Nor do I mean to devalue the importance of changes in feelings as helpful to recovery, but by themselves such changes in feelings make unreliable indicators of improved resistance to life stresses.

Important changes in life situations often occur to patients undergoing psychotherapy. The psychotherapist then has an excellent chance to observe any subsequent changes in the patient's behavior. The ongoing psychotherapy may sometimes make difficult the separation of effects on the patient's behavior derived from the psychotherapy and the effects derived from an apparently important life experience outside therapy. Among my examples I have included a few from patients in psychotherapy, but only when it seemed clear to me that a marked change in the patient's behavior began after some important experience outside the therapy, which experience the patient himself or persons around him had initiated.

I have grouped the examples below under headings which I consider convenient and not necessarily explanatory. Certainly overlapping occurs and other interpretations may prove more valuable than those I have suggested. The examples have in common a marked change in the patient's behavior brought about through his own activity or through experiences in his life outside psychotherapy, although not necessarily independent of it.

EXAMPLES

Desensitization through Recall, Verbalization, and Assimilation of Past Painful Experiences. Many experiences gain and lose their meaning for us by being brought into association with other significant experiences. An event evokes anxiety by reminding us, not necessarily consciously, of earlier threatening events. But it may cease to make us anxious when we bring it into

association with new or old experiences which have other non-anxious qualities. The processes of retroactive interference and assimilation, as Bartlett(11) called them, go on continually. They may proceed with little or no external aid, both consciously and unconsciously(12).

John Stuart Mill described in his autobiography(13) a severe depression from which he suffered when a young man. The depression occurred when Mill realized that his zeal for reform concealed his own interest in himself behind a pretense at improving the lives of others. Guilt, apathy and inertia followed this insight. Mill attributed his eventual recovery after 2 years of illness to the reading of Wordsworth's poetry. He thought that the poems benefited him, first, by evoking in his mind memories of the happy country scenes of his childhood, and secondly, by arousing once again strong emotions which in his depression he had ceased to feel.

Fechner, the great 19th century physicist, psychologist, and philosopher, suffered from a severe depression with hypochondriasis from which he recovered at the end of 3 years of almost total disability. His pupil Wundt attributed Fechner's recovery to autosuggestion(14). The affirmations given in suggestions whether provided for the patient or by himself, constitute new images (or the revival of old ones) that neutralize the effect of the dominant pathogenic images. For this reason I have placed Fechner's recovery in the group with Mill's and the examples which follow.

The processes by which one event, in the present context a painful one, is brought into association with others which are less painful or less injurious to self-esteem, take place more quickly if the sufferer expresses the painful events in words to other sympathetic persons. Sophocles(15) knew this, and so did Shakespeare(16) and Tennyson(17). The relief experienced after confiding one's distress in others has made this an almost universal mode of effective psychotherapy.

Janet, Breuer, and Freud discovered that much relief can occur when the patient recalls and verbalizes not only experiences which he remembers but also those he has forgotten or repressed. Psychopathologists

still dispute whether such de-repression is a requirement of recovery from a psychoneurosis as Freud claimed. All agree, however, that this process often has value in facilitating recovery. It may occur outside psychotherapy as the following example shows.

A 44-year-old woman (not a patient) told me the following story. From early childhood she had repeated nightmares in which she was frantically looking for someone and was extremely frightened at not having found this person. After her marriage in her early thirties, these continuing nightmares kept her husband from sleeping. He finally asked her what she was dreaming. Upon hearing her description of them, he asked her if she had in fact ever been lost. My friend thereupon remembered that when she was 5 years old she had been lost in the bolt goods section of a department store. Being then small, she walked back and forth in the aisles, hidden by the bolts and herself unable to see above them. Eventually she was found. The nightmares began after this episode. After my friend recovered this memory, the nightmares abruptly ceased and had never returned in the 10 years following. No strong emotion accompanied the recall of the childhood experience, and the recall did not seem at the time particularly important. My friend did not expect that it would influence the occurrence of the nightmares and later noted with surprise that they had ceased. The sympathetic interest of her husband may have contributed to the cessation of the nightmares, because my friend not only recalled the episode of being lost, but told it to him.

Desensitization through Association of Experiences which have Aroused Anxiety with New Pleasurable Experiences. An anxiety-arousing (so-called traumatic) experience may be brought into association with new experiences as well as with old experiences remembered and sometimes verbalized. If the patient becomes able to associate the traumatic experience with some new experience which gives pleasure or satisfaction, the previously painful situation loses its capacity to stimulate anxiety. An awareness of not having fled, i.e., of having "mastered" a stimulus for anxiety may accomplish this as the following case suggests whom I treated with psychoanalysis for several years.

A male medical student who had a great many symptoms of anxiety which a wide variety of

situations stimulated was especially prone to anxiety when on display in front of groups of other people. Thus as a medical student he loathed to present his cases on ward rounds and went to great lengths to avoid this. By various means he was able, while a student, to escape from nearly all such situations. For example, when his turn came to present a case, he would absent himself or persuade another student to present his case for him. Although he made much progress during psychotherapy with other symptoms, he made none whatever in this matter.

As the time for his graduation approached, he dreaded the prospect of internship in which situation he knew he would be less able to avoid the situations he feared. In June, he learned to his horror that he had been assigned first to ambulance duty. The prospect of having to go to the scenes of accidents and there administer treatment to injured persons with a large crowd gathered around filled him with severe anxiety. He tried unsuccessfully to persuade a secretary to alter the assignments so that he would not have to take ambulance calls until later, or never. As July approached, his anxiety became greater and greater. But when the first day of internship actually arrived, he decided he had no alternative but to make the best of the situation, come what might. On his first ambulance call he had so much anxiety that he took large amounts of sedatives which he had prescribed for himself. Everything went well, however, and he felt less anxious when the next ambulance trip came up. At each occasion his anxiety became less and he correspondingly reduced his sedation. Within 10 days he had dispensed entirely with sedatives and felt quite comfortable on ambulance calls. Apparently from each of the first ambulance calls he derived a sense of accomplishment which he feared he could not achieve. The recollection of his "successes" made him increasingly confident and, correspondingly, decreasingly anxious as his experience increased.

Herzberg(8) exploited this feature of learning in assigning to his patients series of tasks of graded severity. The accomplishment of each task provided the patient with a sense of accomplishment or mastery which made easier his undertaking and accomplishing the next task. Wolfe(9) has also shown that the gradual but persistent association of pleasurable responses (e.g., sexual pleasure) with situations formerly evoking anxiety will eventually reduce and

abolish the capacity of these situations to evoke anxiety.

Any strongly pleasurable activity or any response which contributes to the reservoirs of self-esteem in a person will tend to neutralize a "painful" experience and thereby reduce or abolish its capacity to evoke anxiety. The following case illustrates this principle.

A man who suffered from a severe claustrophobia determined to overcome this fear and did so in the following manner. He deliberately exposed himself to situations evoking his phobic reaction, e.g., trains, street cars, and elevators. Then he "confessed" his disability to a number of friends singly and in groups. He found relief in learning that many of them had similar fears, and in the acceptance of him by others who had not. This reduced the shame he had felt with regard to his phobia and so increased his self-esteem and confidence. When he felt some initial reduction in his fears of confinement, he began a program of riding on street cars while reading which he had always enjoyed. Gradually he established an association between the pleasurable activity of reading and riding on street cars. This program led to a steady abatement of his anxiety which had completely disappeared within a year of his starting his treatment of himself. He had had no recurrence of anxiety in the 3 years following this before he made his report (18).

Increased Supplies of Respect, Reassurance and Affection from Other Persons. Good fortune may come in the form of new persons and new experiences from which a patient may learn new responses. Boverman has reported in some detail the influence of a kindly ward attendant in facilitating an ostensibly "spontaneous" recovery in a psychotic patient (19). Wolberg has reported another example of the same kind of influence by an attendant (2).

A young student was raised by an ill-tempered and shrewish mother, whose behavior so alienated the patient from women that he considered himself at the time of entering therapy doomed to homosexuality. He had almost no social relationships with girls and they had never got beyond the slightest physical contact. He seemed to select girls who were as inhibited sexually as himself. Not long after he began treatment he moved from one boarding house to another. Soon afterwards, an attractive girl

moved into the next room of the boarding house. They became acquainted and the friendship grew. They discovered that when they unlocked the connecting door between their rooms they could be together more often. The girl was outgoing and warmly affectionate. She was also experienced in the ways of sex and almost before the patient knew it, she had enticed him (or seduced him) so that he was soon enjoying sexual intercourse while entirely forgetting his fears of being a homosexual. They were eventually married.

In this case, a girl sufficiently different from the patient's mother and previous girls he had known provided pleasures sufficiently great to overcome his sexual inhibitions. By taking the initiative herself, she had largely compensated for his passivity. The mastery of his fears of sexuality brought the patient increased confidence which enabled him to handle better other sources of his anxiety.

The marked difference in capacity for affection between his girl friend and his mother may additionally have helped the patient to correct faulty generalizations about women which he had carried over from his experiences with his mother. Kolb and Montgomery (20) have reported an instance in which a patient's apparently spontaneous improvement coincided with his correcting his misperception of his therapist through having a different, more friendly, less formal exchange with him outside the standard therapeutic period.

The awareness of affection, aid, confidence, and other factors usually described under the heading of "support" often seems to permit human beings to face anxiety-provoking situations which they would otherwise avoid. Wolpe (9) has described the overcoming by his small son of a fear of jumping from a 3-foot wall. The fear came on after the boy fell from the wall once, and it continued until his father persuaded him to jump first while he held his hand and then merely looked on without holding the boy's hand. After a dozen jumps the boy jumped from the wall fearlessly even if his father were not present.

Situations of this kind often include several ingredients. In this case, the boy may have jumped again to please his father, also because his father held his hand. The desire

to preserve the affection and respect of new (or old) friends and acquaintances may account for some instances of recovery which are referred to in the literature of psychoanalysis as "transference cures." As children often attempt unpleasant tasks in order to please their parents, patients may undertake new behavioral responses to please other persons who may or may not be psychotherapists. These new responses may then bring additional gratifications which serve to reinforce the new behavior after the original stimulating relationship has ceased.

The cases of this group may resemble those of the last group in the process of improvement. The friendly, supportive person may provide a new stimulus of pleasure with which the previous anxiety-producing stimuli become associated as a result of which the latter lose their capacity to arouse anxiety. I have, however, grouped them separately because of the possibility that the supportive person by his interest in the patient exerts a generally beneficial influence through altering the patient's "self-concept." As the patient then begins to entertain different thoughts about himself he becomes less sensitive to previously stressful events and better able to encounter them adaptively.

Something of this kind seems to have occurred in the case of a depressed soldier during the Crimean War.

The soldier had participated in the charge of the Light Brigade at the battle of Balaclava. Subsequently he had become depressed and this, the camp physician believed, prevented his recovering from the effects of an injury he later received. An attempt to discuss with the apathetic soldier the charge in which he had participated elicited only monosyllabic replies. Tennyson's poem on the charge was then read to him and immediately kindled an animated response. The patient "entered upon a spirited description of the fatal gallop between the guns' mouths to and from that cannon crowded height." Within a few days the patient had entirely recovered and was discharged from the hospital. The camp physician attributed his recovery to the effects of hearing Tennyson's poem (21).

More than two-thirds of the soldiers in this charge were killed. The survivors

seemed to have experienced afterwards a state of shock to which several factors must have contributed. The experience seems to have had for the survivors a traumatic effect not only in the physical sense but also psychologically (22). Guilt over the failure of the charge and the deaths of comrades entered into this. Tennyson's poem diminished emphasis on the folly and failure of the charge and placed it on the discipline and heroism of those who participated. Thus the reading of the poem to the depressed soldier may have altered radically his view of himself in relation to the charge and thereby restored his self-esteem.

New Models of Behavior. Although men have known for centuries that children learn to speak through imitating adults, psychopathologists have only recently begun to emphasize the learning through imitation of other kinds of behavior, including abnormal behavior (23, 24, 25). Deprived of adequate models children may not learn what their more fortunate contemporaries learn; but they may still catch up. Thus, in a long-term follow-up study of untreated shy and introverted children, Morris, *et al.* (26) found that the majority had "recovered" by or in adulthood and were leading normal lives. Many had lost their shyness and had become outgoing, apparently as a consequence of having married more gregarious wives.

A patient of mine had lost her mother when she was 13. She had fallen under the rather tyrannical dominance of her father and had afterwards lacked close contact with mature women. As a consequence, she became stunted in the development of feminine qualities and failed in her early relations with men. At 29 she had not married and sought therapy. Two years of treatment prepared her for an opportunity which occurred outside the therapy. She joined the social club of a church and there found new models for feminine behavior among persons of her own age. A marked acceleration of her feminine development followed her joining this club and within a few months she was dating eligible men regularly. Shortly after this, she selected one as superior to the others, became engaged to him, and some months later married him. His mother proved an unusually kindly and sensitive person to whom the patient became warmly attached before and after her marriage. The pa-

tient's mother-in-law seemed to assist further the patient's feminine development by acting as another, if delayed, substitute for the patient's mother.

New Situations Requiring Different Responses. The loss of supportive persons through death, defection, or other kinds of separation, seems often to contribute to recovery from the psychoneuroses. Many persons have experienced a marked acceleration in their own maturation with the death of a parent which obliged them to live differently and more responsibly. The death of Freud's father seems to have freed him from certain inhibitions affecting his work (27). Other, lesser separations such as going away to school, college, work, or the armed services, have facilitated maturation by requiring new and more independent behavior. Usually the changes so wrought occur gradually; sometimes turning points seem clear, as in the following example.

A medical student I treated had strong feelings of inferiority with severe anxiety regarding his capacity to perform medical procedures. He believed himself hopelessly lacking in the necessary manual skills. Between his third and fourth years he took an externship at a distant hospital and I did not see him for several months. When we met again he showed much less anxiety and exuded such unusual confidence that I questioned him carefully about what had happened. He said that the hospital had a very small staff and the administrators had given the externs responsibilities far beyond those their training called for. Although initially frightened, the patient had undertaken all his assignments including the management of some serious emergencies. He especially recalled one occasion when a patient began to bleed profusely from an operative wound. In the absence of anyone more competent the extern was called to stop the bleeding. Upon first hearing of the hemorrhage he wanted to flee. Nevertheless, he had gone to the patient and eventually arrested the bleeding. This and other similar experiences, he thought, had greatly reduced his anxiety and increased his confidence.

Sometimes exasperation or changed circumstances modify the attitudes of those around a patient so that they come to expect or even demand a different kind of behavior from the patient. Two rather dif-

ferent examples of this have occurred in my collection of these cases. "

A friend told me that in the early years of his marriage when he and his wife quarreled, she would completely abandon the housekeeping and would stop preparing meals, making beds, and washing laundry. All this inconvenienced him greatly and he tried with many arguments to make her see that she should not neglect her responsibilities when angry since he continued to discharge his. As his persuasive efforts failed, he finally became sufficiently annoyed to tell her that the next time she shut down her housekeeping, he would cut off her access to funds in their checking account at the bank. His wife now protested in her turn about this unfairness, as she believed it to be. Nevertheless, this threat became a turning point in her behavior. With occasional mild relapses, she thereafter kept up her housekeeping even when angry with him. Her husband, on his side, finally realized that her neglect of housekeeping was, among other things, a protest at his failure to help her with its more burdensome aspects. He began to assist her more so that housekeeping became less of a chore for her. This couple thus achieved a kind of *therapie à deux*.

A different kind of expectation occurred in the case of the son of one of my patients, who told me the following story.

At the age of 22, the son experienced a severe depressive reaction, which seems to have been precipitated by the induction of his brother into the armed services during the second world war. He, himself, had wanted very much to go into the armed services but could not do so because he was assigned to essential work in an aircraft factory. He became preoccupied by thoughts of inadequacy and inferiority in relation to his brother, and these developed into a severe depression. Following the onset of the illness, he spent about 3 of the next 6 months in a hospital receiving psychiatric treatment. The rest of the time he received treatment as an outpatient. At the end of 6 months, however, his condition had not improved; he continued quite depressed and withdrawn. At this time his father decided to bring him home, apparently with the concurrence of the patient's psychiatrist. The son returned home and his father intended to give him a position in his flour mill. He had realized that his son could not, in his mental condition, handle a responsible job and so had planned to give him some relatively minor position, al-

most a sinecure. The son had been home only a few days when his father took him on an automobile trip to attend to some business matter. The son, still very depressed, had apparently gone along only for the ride with his father. On the trip an accident occurred which rather severely injured the father's right hand. He was also knocked unconscious for a brief time, but the son was not injured at all. The disability of the patient's father obliged him to ask the patient to do various things for him which he had not intended to assign to him. Among other things he had to ask his son to sign checks and letters since he could not use his right hand. Within a few days the patient's depression began to lift and cleared entirely shortly afterwards. The son took up eagerly the responsibilities put on him by his father.

The father, in telling me the story, said that in his opinion his son's recovery was due to his getting a sense of being needed by his father when the father became injured. Previously, the son had been given a job more or less out of charity by the father. After the father's accident the father needed the son to help him because he could not do various things himself with his disabled hand. The son responded to this need which counteracted his sense of being useless when his brother had gone into the armed forces. No relapse had occurred in the 15 years following this recovery.

Wolberg briefly reported a similar instance of spontaneous recovery when a patient was asked to care for other patients with a consequent rise in her self-esteem (2).

Shifts in Motivations Brought About by Fear, Shame, or Desperation. Sometimes a progressively destructive course of behavior may be arrested by some event which shocks the patient into an awareness of the harm he does to himself and others.

A woman who had been drinking alcohol excessively for at least 6 years required a gall-bladder operation. Her husband, who was a physician, conspired with the surgeon to inform the patient after the operation that the surgeon had discovered in her liver the signs of early cirrhosis. The fear aroused by this fiction shocked the patient into complete abstinence which continued for the following 7 years, that is, to the time I heard the account.

Another alcoholic patient fractured his leg during a brawl when drunk. The leg healed slowly and kept him disabled for almost a year.

He thereafter remained a teetotaler for at least 10 years during which time he was followed by his physician.

A patient developed a phobia of buses so that he was obliged to walk to work. This phobia had arisen through a chain of associations from anxiety stimulated by the patient's wife. The patient did not tell his wife that he had become afraid of buses because he greatly feared her derisive laughter. He gradually became less afraid of his wife and more assertive with her, but persisted in his fear of buses. One day he was in the shopping district of his city with his wife when it was most convenient for them to return home on a bus. Rather than expose his phobia to his wife, the patient got into the bus with her and went home. Thereafter his fear of buses rapidly diminished and soon disappeared altogether.

CONCLUSIONS

The foregoing examples by no means exhaust the possibilities with regard to spontaneous recovery from the psychoneuroses. They may suffice, however, to show the existence of many opportunities for patients to have experiences apart from psychotherapy which can stimulate or facilitate new behavioral responses necessary for recovery.

Two implications from the study of such cases emerge. First, any satisfactory theory of the processes which enter into the origin of psychoneuroses and recovery from them must be capable of accounting for instances of spontaneous recovery. For example, it can no longer be maintained that de-repression of past painful experiences is a requirement of recovery, although this may under certain circumstances contribute to it. Nor can spontaneous recoveries be generally attributed only to the operations of suggestions from other persons, an interpretation which seems often to be implied in the use of the concept of "transference cure."

Secondly, these cases seem to establish further the value of life situations outside the therapist's office for experiences valuable in unlearning maladaptive behavior and learning new behavioral responses. This value justifies a careful study of them by therapists and encouragement by them of their appropriate exploitation as a means of accelerating recoveries from the psychoneuroses.

SUMMARY

1. Several independent studies of untreated psychoneurotic patients have shown that between 40 and 60% of such patients recover within a few years of the first observations of their conditions. Treated and untreated patients probably recover through the same processes which include and require the learning of new behavioral responses. We have some evidence that treatment which emphasizes the practice by the patient of new behavioral responses in periods between his therapeutic sessions will shorten the number of interviews required and possibly the total duration of the illness.

2. Examples are given from some 20 cases of spontaneous improvements or recoveries derived from observations or reports of patients, experiences of other persons, or published accounts of such recoveries.

3. The following circumstances or processes seem to facilitate recovery from psychoneuroses: (a) desensitization through recall, verbalization and assimilation of past painful experiences; (b) desensitization through association of painful experiences with new pleasurable experiences; (c) increased supplies of respect, reassurance, and affection; (d) entry into the patient's life of new models of behavior; (e) occurrence in the patient's life of new situations requiring different behavioral responses; (f) shifts in motivation brought about by fear, shame, or desperation.

4. Further study of so-called spontaneous recoveries from mental illnesses may teach us much more about experiences which prove valuable to patients. From this we may learn more about what we need to do to assist patients to recover more rapidly than they would without psychotherapy.

CERTAIN SOCIOCULTURAL AND ECONOMIC FACTORS INFLUENCING UTILIZATION OF STATE INSTITUTIONAL FACILITIES IN INDIANA¹

JOHN I. NURNBERGER, M.D., M. ZUCKERMAN, Ph.D., J. A. NORTON, Ph.D.,
AND H. M. BRITTAIN²

INTRODUCTION

This study is preliminary to a long-range investigative program concerning the following hypotheses: The process of identifying an individual as a psychiatric patient requiring institutional care is a function of social, cultural and economic factors in his environment. An individual from a culturally sophisticated and socioeconomically stable environment will be identified as a "patient" more probably because of inner distress and its socially eccentric manifestations. One from a less sophisticated milieu at the opposite socioeconomic extreme will be identified as a "patient" more probably because of behavior aggressively directed toward his environment. Another more familiar way of stating this hypothesis is that the environmental tolerance for and interpretation of individual behavior is closely correlated with those factors which influence or determine attitudes toward mental and emotional disturbance.

The State of Indiana is favorable for testing such hypotheses. The range of relevant social, cultural and economic variables is broad. In order to lay the groundwork for testing these and related propositions, a systematic description of Indiana's counties was developed. In the present report, certain county characteristics will be described as well as the patterns of their relationships within the state. It is the secondary purpose of this study to report certain relationships between these factors and annual admission rates to the state mental institutions:

Albee(1) has recently reviewed data for the United States at large which reveal no significant correlation between average first admission rates to state institutions and the

urbanization rankings of the states involved. His extremes include the 10 most highly and least highly urbanized states in the U. S. A. This national study points up a clear and direct correlation between state urbanization and *per capita* income on the one hand, and median years of schooling completed on the other. Locke and associates(11) conducted a study, not only of average annual first admission rates for all diagnostic categories, but also for those diagnosed as schizophrenic. This study of the Ohio State hospital system was for a recent 4½ year span. Data were analyzed along 2 major dimensions: metropolitan-nonmetropolitan, and high-low rates of hospital usage. These axes are partially reflected in the zonal analyses of state hospital admission rates. Carstairs and Brown(2) studied differential utilization of community psychiatric facilities shared equally by 2 contiguous regions in Wales, one a population-dense mining community, and the other a rural-agricultural community. The advantage of studying the impact of social and economic variables in instances where the available resources for psychiatric care are equally shared by differing regions is obvious. The relative isolation and legal provisions for admission within several state institution zones in Indiana made possible such a limited analysis with the present data.

There appears to be an inverse relationship between the number and range of pertinent descriptive variables selected and the cogency of meaningful inferences to be drawn concerning their selective contribution to institutional usage. Clausen(3) has emphasized that the number of significant, or near-significant, correlations between social, economic, educational and other local variables with hospital admission rates is very great indeed, but that our understanding of psychiatric disorders at this level is little enhanced by such data. He has stated

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² From the Institute of Psychiatric Research and the Department of Psychiatry, Indiana University Medical Center, Indianapolis, Ind.

that it is not currently possible to specify clearly the relationship of prevalence of psychotic disturbances with any specific aspect of the environment along such social dimensions. He also expresses the opinion that the *interpretations* of statistical correlations are often made on a *post hoc* basis and yet presented as virtually self-evident. It is generally held that conclusions concerning the social determinants of serious emotional disorders can rarely, if ever, be drawn on the basis of any type of admission rate statistic. Such a tendency often intrudes in the most critically reported studies (13, 11, 2), but it militates against the objective interpretation of social factors. On another level, there is strong temptation for the worker in this area to infer generalization for one or another social or cultural determinant of disturbed behavior, while he stresses, paradoxically, the specifying conditions for its expression. The present study supports the conclusion that a relatively unique environment is required for the optimal expression of the social, cultural, or economic factors selected as variables influencing institutional usage or availability.

MATERIAL AND METHODS

The bulk of information used to categorize the various counties was derived from "Statistical Abstract of Indiana Counties" published by the Indiana State Chamber of Commerce, June, 1954. The following specific variables collected there were from the 1950 U. S. Census of Population: population density, percent urban population, occupation of employed workers, and school enrollment percentages by age groups. Information on average wage, which was incorporated in the economic index for each county, was obtained from official information releases published by the Indiana Department of State Revenue as of 1949. Data on farm operators, farm acreage and value, also included in economic index calculations, were obtained from the United States Census of Agriculture, 1950 (Counties and State economic areas, Indiana). Change in acreage value of farm property during the period 1950-1954 is reported in the 1954 Census of Agriculture of the U. S. Department of Commerce, Bureau of the Census, Washington (1956). Data on population

mobility in the period 1950 to 1956 were calculated from the Indiana State Board of Health, Division of Statistical Research, 1956, Population Release No. 3 (March 1, 1957). All calculated estimates of change were corrected for natural causes, that is, births minus deaths, for each county. The 1956 estimate of population from the same source was used as the population base for calculating annual admission rates for the period 1956-1957 and 1957-1958, while similar data from the 1958 population release were used as the base for calculating annual admission rates during the year 1958-1959. All data on admissions to Indiana state institutions were obtained from the Office of Statistical Research, the Indiana Division of Mental Health for each of the 3 years from June 30, 1956, to June 30, 1959. The annual admission rates referred to in this study include all admissions except for transfers between institutions. A certain percentage, therefore, represents readmissions during or between annual periods.

The selection of the school enrollment factor deserves special comment. In certain studies which survey social factors, the conventional statistic is median school years completed by persons 25 years of age or older. There are certain major limitations implicit in this statistic. The distribution is not sufficiently specified, and perhaps more importantly, the age of completion of schooling is neither indicated nor inferred. In clinical evaluation and prognosis, a much more useful indicator in our experience has been the school-enrollment status at age 16 to 17 years. Indiana state law requires all residents to continue formal schooling to the age of 16. County enrollment percentages show widest variations in this age interval. Moreover, since Indiana has many small colleges and at least 3 major universities, this variable successfully isolates artificial and discontinuous increments in school enrollment reflected in the age group 18 years and above. Actual percentage still enrolled in school in the age range 16 to 17 varied from 22.8% to 93.3% in the extremes counties.

The economic index calculated for each county was derived from 5 separate occupational, income, and farm value categories. The occupational categories included a high and a low status group. The high status

group was composed of professional, special technical, nonfarm managerial, and proprietor personnel. In the state at large, approximately 15% of all employed personnel, 14 years of age or older, were in this group (Group I); Group III included all those 14 years of age or older employed in domestic or other services, unpaid farm laborers, employed farm laborers, and other types of day laborers. In the state at large, approximately 20% of all employed were engaged in these occupational activities. The formula for calculating the economic index is as follows:

$$\begin{aligned} \text{Economic index} = & \frac{1}{\frac{I (\text{Total number}) \times 6.5}{\text{Total employed}}} + \frac{III (\text{Total number}) \times 5}{\text{Total employed}} \\ & + \frac{3000}{\text{Average wage}} + \frac{(\text{Total Farm Owners} + \text{Part Owners}) \times 10}{\text{Average value of land and buildings/farm}} \\ & + \frac{1.43}{\frac{\text{Average value farm land and buildings/acre (1954)}}{\text{Average value farm land and buildings/acre (1950)}}} \end{aligned}$$

The value 1.43 is the ratio of average values for farm land and buildings per acre for the state as a whole and for the years indicated.

Inspection of each component in this 5 factor sum reveals the single process of derivation. Thus, for the factor involving occupational Group I employed, that county which has the same proportion employed in this group as in the state as a whole, receives a numerical value of 1. If the proportion so employed is below the average for the state, the numerical value of the factor will be greater than 1, while it will be less than 1 in a county with greater than average representation in this occupational group. The factor dealing with the fraction employed in occupational status Group III is larger than 1 if the total so employed in this group for the individual county is greater than in the state as a whole, the value being less than 1 if the fraction is less than in the state as a whole. The remaining 3 factors are so arranged to be entirely consistent with the first 2. It will be noted that the economic index includes not only data relevant to oc-

cupation, but also to wage and farm property evaluation. No attempt was made to weight the separate elements in this expression. Approximately equal emphasis was placed on occupational status and farm evaluation because Indiana is not only an active industrial center, but also, a rich and important farm state. The economic index for a county which very closely follows the over-all state trend will be approximately 5.0 while a relatively more prosperous county with high percentage in occupational status I and/or richer farming land will have an economic index less than 5. A county at

the opposite end of the economic scale will have an index value higher than 5.0. The actual numerical value ranged from 4.29 in the most prosperous county to 8.68 in the least prosperous county with an actual mean of 5.50. The index figure has only relative ranking value and was used only for this purpose.

In preparing the descriptive items for statistical treatment, each of the 92 counties was rank-ordered along a number of dimensions. For the data of Table 1, rank-orderings were on the basis of population density per square mile, estimated population shift from 1950 to 1956, etc. For each variable, the counties were systematically ranked with the lowest ranking assigned to the lowest actual value for the variable. For example, the 92 counties were ranked from No. 1 (lowest population density per square mile) to No. 92 (highest population density per square mile). Along the dimension, estimated population shift from 1950 to 1956, the county ranked 1 showed the greatest net loss in population during the 6-year period, while the county ranked 92 showed

the greatest net increase in population for the same period. Similarly, as in Table 3, all counties were rank-ordered along the economic index axis from No. 1 (highest numerical value of the economic index) to No. 92 (lowest economic index).

In order to test for clustering of individual variables, Spearman Rank-Order Correlations were calculated for the 6 variables in Table 1, and the level of significance of intercorrelations justified the establishment of one combined urbanization variable and of 2 other unitary variables. In calculating significance of differences between means of Table 2, a conventional "t" test was applied.

For the data of Table 3, Spearman Rank-Order Correlations were calculated for within-zone variables with a conventional "t" test of significance for correlations used. A special technique for pooling rank-order correlations across zones with tests of correlation significance calculated as ordinary product moment correlation coefficients, and with degrees of freedom appropriate to the pooling, was applied.

OBSERVATIONS AND DATA

The 92 counties of the state were each described in terms of their rank order along the axes of population density per square mile, estimated population shift in the 6-year period 1950 to 1956, percent of population in urban areas, percentage of total employed in agriculture and manufacturing occupations, and the percentage in age group 16-17 years still enrolled in school. To explore homogeneous clusters of these variables, Spearman Rank-Order Correlations were calculated. These are summarized in Table 1. An inspection of this table reveals high level correlation between popula-

tion density per square mile, percent of population in urban areas, and percent of total employed in agricultural occupations. There is a somewhat lower level correlation of these 3 factors with the percent employed in manufacturing. Because these 4 factors appeared to form a crude correlation cluster, the individual rank-orders for each element were added, and the mean rank-order for the 4 variables was used as the measure of mean urbanization rank. The urbanization variable referred to in Figure 1 and in Tables 2 and 3 is, therefore, a combined factor. Estimated population shift during the interval 1950 to 1956 correlated significantly with all the urbanization factors, but at a consistently and significantly lower level, 0.3. This factor was, therefore, treated as a separate descriptive variable in subsequent analysis.

It is interesting to note that there was no correlation between the variable, percentage still enrolled in school aged 16-17, and any other variable noted. This absence of correlation was not anticipated, but, because of it, the school enrollment factor was treated as a separate social variable.

The economic index factor was not introduced into the correlation matrix of Table 1. Because this economic factor was a complex empirical composite, it was thought wise to treat it as a separate factor.

The 18 counties at each ranking extreme for urbanization, population mobility, percent still enrolled in school, and economic index, are plotted on a county map reproduced in Figure 1. It will be noted that the 18 most highly urbanized counties are distributed without pattern throughout the state. A cluster of highest-urbanization counties is seen in the northern (top) end of the state adjacent to the Gary-

TABLE 1

Hammond-Chicago steel mill region. Another loosely associated group extends across the central portion of the state following the historically important transcontinental trade route, and generally centered on the capital county of the state (Marion County), which, incidentally, is the third

most highly urbanized county. Two highly urbanized counties are distributed along the commercial Ohio River course in the extreme southern portion of the state.

A cluster of least highly urbanized agricultural counties is noted in the extreme northwestern portion of the state in the

FIGURE 1
Distribution of Those Indiana Counties Ranked at the Extremes (18 Highest and 18 Lowest Rank-Ordered) for the Following Variables:

- Urbanization : Highest 18-diagonal lined
Lowest 18-stippled
- Economic index : Highest 18-Circled H (Lowest numerical values)
Lowest 18-Circled L (Highest numerical values)
- Population mobility : Highest 18 (greatest net population gain)-H (at left of two-letter sequence)
Lowest 18 (greatest net population loss)-L (at left of two-letter sequence)
- School enrollment : Highest 18 (highest % of those aged 16-17 years still enrolled)-H (at right of two-letter sequence)
Lowest 18 (lowest % of those aged 16-17 years still enrolled)-L (at right of two-letter sequence)

heart of the state's richest agricultural area. The remainder of the counties ranked at the lowest extreme in urbanization are distributed irregularly through the central and southern portions of the state with a considerable number bordering the Ohio River.

There is a noteworthy geographical localization of the counties ranked at the extremes for population mobility. The majority of the 18 counties showing greatest net increase in population, that is, positive mobility, are in the central region of the state adjacent to Marion County. These counties had a net population increase ranging from 5% to 20%. In contrast, the majority of the 18 counties extreme for net population loss are along the perimeter of the state.

The geographical discrimination of the counties ranked at the extremes for school enrollment is quite clear-cut. Of the 18 counties ranked highest in school enrollment, all except 2 are in the northern half of the state. Fifteen of the 18 counties ranked lowest in school enrollment are in the southern half.

The north-south differential is even more conspicuous for counties by economic index ranking. All 18 counties ranked lowest in economic index are southern counties. Only 3 counties ranked highest in economic index are southern counties, the remainder being either junction or northern counties.

Inferences concerning the availability and utilization of state institutional facilities were drawn from statistics on mean annual state rates for the years 1956-1957 through

1958-1959. Annual admission rates for this 3-year period were averaged. No corrections were applied to transform these into standardized rates, nor were corrections for local variations in age or sex distributions within the relevant populations attempted. The institutions involved, to which data reviewed in Table 2 apply, include 7 state mental hospitals, one of which is a small, acute treatment and diagnostic center serving the entire state, and another, a state hospital serving only Marion County. The remaining 5 mental institutions are distributed around the periphery of the state. Each serves from 13 to 25 contiguous counties (Table 3). The remaining institutions include a small centrally located state facility for alcoholic patients, a northern and a southern state school for the mentally retarded, and one centrally located hospital for those with convulsive disorders. Patients in these institutions range from infancy to old age. Admissions were not subdivided by diagnostic categories. Therefore, age, sex, or standard population corrections were neither feasible nor indicated. Such corrections (8) have not infrequently been used in reporting admission data (5, 6), and in special circumstances, they are justified and even necessary. Diagnostic categorical subdivisions were considered unimportant to this study and notoriously unreliable. Gregory (5) has summarized the lack of consensus on diagnostic categorizations for such a major category as schizophrenic disorders, which makes for confusion in the interpretation of such data.

TABLE 2
Mean Annual (1956-1959) State Hospital Admission Rates for the 18 Counties Ranked Highest (H) and Lowest (L) in Selected Socioeconomic Categories

SOCIOECONOMIC CATEGORY	MEAN ANNUAL ADMISSION RATE (MEAN ADMISSION/10 ⁴ POPULATION)		SIGNIFICANCE OF DIFFERENCE OF MEANS
	HIGHEST 18	LOWEST 18	
1. Urbanization	99.0	103.0	n.s.
2. Population Mobility	93.0	93.0	n.s.
3. School Enrollment	84.0	107.0	Difference significant at <.01 level
(a) Mean Economic Index of Counties under 3 (See Text)	5.28	6.30	Difference significant at <.01 level

Two types of analyses were carried out. In one, the impact of extremes in socioeconomic and cultural variables on the utilization of available facilities was evaluated, assuming that local or zonal characteristics influencing case identification and admission were approximately homogeneous. Mean annual state institutional admission rates for the 18 counties ranked highest and lowest in selected categories are recorded in Table 2. For the 18 counties ranked highest and lowest in level of urbanization, the mean annual admission rates were virtually identical during this 3-year period. The population pool provided by the 18 counties ranked highest in urbanization was 2,660,000 in contrast with a pool 10 times smaller, i.e., 256,000 provided by the 18 least urbanized counties. There was likewise no significant difference in mean annual admission rates for those 18 counties ranked most positively mobile (with the highest positive influx of population) as contrasted with the 18 showing greatest net population loss. Since these extremes both reflect approximately equal but oppositely directed mobility, a critical analysis of the interaction of this factor with state hospital utilization is not possible (see Table 3 for a selective analysis). Among the 18 counties ranked highest in school enrollment, the mean annual admission rate is significantly lower than for the 18 counties ranked lowest in this variable. The mean economic index of the counties ranked highest in school enrollment was significant-

ly lower (higher economic status) than in the 18 counties ranked lowest in school enrollment.

At this juncture in the analysis it was proposed that the suggested differential utilization and/or availability of state hospital facilities on an educational-economic basis might be a zonal or geographic characteristic. Indeed, as already noted, the majority of high school-enrollment counties are in the northern half of the state and the majority of lowest school-enrollment counties are in the southern half.

To clarify the possible independent influence of the geographic factor, a separate analysis of mean annual admission rates for the 5 mental hospitals of the state serving a total of 91 counties was separately evaluated. These data are reviewed in Table 3.

Indiana state law requires that a person identified and accepted as a candidate for state hospital admission be admitted first to the state hospital serving his county. In rare instances, exceptions to this rule occur for Evansville, Madison, and Richmond. These 3 institutions accounted for approximately 31% of all state admissions during the 3-year period under consideration. The total admissions to the 5 institutions under consideration was 9,465, or 74% of all state institutional admissions. In the 3 state mental institutions referred to above, out-of-zone admissions ranged from .35% to 1.1% of all admissions during the period. It is evident,

TABLE 3
Spearman Rank-Order Correlations Between Mean Annual (1956-1959) State Hospital Admission Rates and Selected Socioeconomic County Variables: Within East State Hospital Zone and Pooled-Across Zones (See Text)

ZONE	N (NUMBER OF COUNTIES)	URBAN- VARIABLE	SCHOOL ENROLL. VARIABLE	POPULATION MOBILITY VARIABLE	ECONOMIC INDEX FACTOR

** $P < .01$.

*** $P < .001$.

therefore, that only rarely are exceptions made to the state admission law in these institutions. Out-of-zone admissions are somewhat more common to Beatty Hospital which maintains a maximum security division for the entire state. During the 3-year period under consideration, approximately 9% of all admissions to this hospital were from out-of-zone counties. The Logansport State Hospital maintains an extensive treatment service for those with problems related to alcoholism, and 21% of admissions to this hospital were from out-of-zone counties.

In the within-zone analyses of Table 3, one outstanding characteristic is that the interaction of the various social and economic factor rankings with institutional admission rates is patterned in a relatively unique way for each state hospital zone. Consider the significant or possibly significant correlations first. In Zone L, for example, population mobility is inversely correlated with mean admission rate. This is true also of Zone M. The trend is not constantly maintained for Zones R, E, and B, and, in fact, is in the opposite direction though not at a level approaching significance. In the pooled, across-zones analysis, this factor appears to be a significant variable at the 5% level, and might, thus, suggest a general state trend. However, the within-zone analysis would suggest that the specific expression of this social factor is intimately dependent upon other regional variables. The same conclusion is justified with respect to urbanization. In Zone R, there is a significant positive correlation between mean admission rates and urbanization ranking, which trend is reflected in Zones L and E, but not in Zones M and B. The school enrollment rank-order is significantly and inversely correlated with mean hospital admission rate in Zone M, reflecting a similar over-all trend across zones. This trend is likewise confirmed by the extremes analysis of the impact of this factor summarized in Table 2. Even here, however, the variable expression of this factor is more clearly revealed when analyzed on a zonal basis. It would appear to be a variable of little or no importance in Zone B, for example, although the trend is generally confirmed in Zones R, L, and E.

An inspection of the data of Table 3 indi-

cates that the combined rank-order correlation patterns are individualized for each of the within-zone analyses. These patterns lend some support to the conclusion that the interaction and significance of such factors as related to the identification and acceptance of an individual as institutionalized patient vary widely with other local circumstances. Some of these patterns are, of course, simply chance fluctuations of the correlation statistic.

DISCUSSION

The data reported here could not be interpreted as reflecting the incidence or prevalence of any disorder justifying institutional management in the areas noted. Only a systematic sampling of representative populations, as, for example, that conducted by Cole and associates(4), could provide useful information on prevalence. Moreover, even with regard to those identified as patients in treatment, these data concern a limited sample of the total. Data on the total number of psychiatric patients in treatment are few. Hollingshead and Redlich(9) reported, for example, that 68% of those persons identified as under psychiatric treatment from the greater New Haven area were under such treatment in state institutions during the 6-month period of their study. One could quite safely infer from the relative distribution of treatment facilities available to the greater New Haven area, as compared with those available in the State of Indiana, that the relative percentage of the total under treatment accounted for by state institutionalized patients in Indiana would be unquestionably higher than 68%, but how much higher cannot presently be estimated.

Inferences concerning morbidity incidence from admission data would presume immeasurably more information than these data provide. Most workers(3; 11, 5, 6, 7, 10, 12) are thoroughly cognizant of this problem, and the matter requires no reevaluation. It is becoming increasingly clear, moreover, that information concerning interaction of whatever social variables with admission rates, even in carefully circumscribed communities(7, 14), should be generalized only with great conservatism. It is worth noting that Locke and associates(11)

report a negative correlation between mean institutional admission rate and mean regional educational achievement for all diagnostic categories in their study of Ohio State mental hospitals. The present study would seem quite clearly to confirm this general conclusion. Nonetheless, the variable expression of the school enrollment factor on a zonal basis suggests that local circumstances may either enhance, reduce, or even neutralize the independent impact of this factor.

SUMMARY AND CONCLUSIONS

Indiana's 92 counties have been described in terms of certain social, cultural and economic variables.

1. Spearman Rank-Ordered Correlations of 6 of these variables justified the inclusion of 4 unit variables under a single composite category called the urbanization factor.

2. Net population change during the period 1950-1956 was isolated as a distinct variable which correlated at a low but consistent level with urbanization. No significant correlation* was noted between a sensitive measure of county educational status (% of those aged 16 to 17 still enrolled in school) and the other social variables studied in the state at large.

3. Counties at the extremes of urbanization followed no recognized geographic patterns of distribution. Those counties extreme for negative population shift were generally located at the periphery of the state, while those showing maximum influx of population during the same period tended to be centrally located.

4. Counties with the highest percentage still enrolled in school were located in the northern half of the state, whereas, those showing lowest enrollment in school were distributed in the southern half of the state.

5. A similar north-south discrimination of counties at the extremes of economic status also was noted.

6. An analysis of the independent impact of urbanization on state hospital admission rates, presuming homogeneous distribution of equivalent resources, reveals no differences in admission rates for the 2 groups of counties at the extremes of urbanization. The lack of interaction here may well reflect the fact that the urbanization extremes studied

died are insufficiently *extreme* to reveal an independent influence of urbanization, as has been shown in certain previous studies.

A similar analysis revealed no significant effect in those counties extreme for population mobility, but did indicate a significant inverse correlation between school enrollment and institutional admission rates.

A separate reanalysis of the interaction of these social variables with admission rates for each mental hospital, and its admission zone as a geographic and institutional unit, revealed that zonal admission rates were correlated in highly individual and specific ways with zonal socioeconomic and educational characteristics. A generalization justified by these data is that certain common sociologic variables, even at the extremes of a normal distribution, will find significant expression in their impact on the level of utilization of the state mental institution, only in a highly specific context.

DISCUSSION

JOHN E. DAVIS, M.D. (Philadelphia, Pa.).—The present paper represents another step forward in the process of attempting to define and understand the complex social factors which are involved in decisions to seek psychiatric treatment. This search for significant parameters, other than the personal and the dynamic, is assuming greater and greater importance as psychiatry is confronted with exploding populations, migrating populations, back-from-the-suburb populations, and beatnik populations and as psychiatry is asked to take a social leadership role not only in alleviating the personal human and social distress which leads to mental illness, but in suggesting ways in which mental breakdown can be averted.

Perhaps it is a sign of confidence in the new drugs and the many other treatment methods that has enabled us to lift the horizon from the personal to the population as a whole, or perhaps it is with a sense of overwhelming despair that psychiatry realizes that considerable energy must be devoted to questions about those who come to mental hospitals. We know that it is not sufficient to have first class institutions without knowing a great deal about the characteristics of the population they are to serve.

The contribution of Dr. Nurnberger and his colleagues with this paper is, first, the derivation of an economic index by which to classify and compare populations. There are several difficulties with such indices. They are generally arbitrary, if well meant, and, in common with any classification scheme, they may obscure more significant but less noticeable real differences. If the index is intended as a preliminary tool with which to approach data, and if the tool itself remains as suspect as the data until established, then there is no real difficulty. Such indices do remind us that the tools of investigation in social psychiatry need as much research into as the object of the survey or research. Fortunately Dr. Nurnberger has given ample discussion as to the nature of the eco-

nomic index so that we can judge its appropriateness when we plan to use it in other investigations. Similar things could be said about the other dimensions of measurement used in the study.

One of the comparisons made by Dr. Nurnberger was between counties which showed high mobility, *i.e.*, moving in or out of the county, and showed no differences in mean annual admission rates. Since mobility has always been considered an important variable, it may be appropriate to report briefly on a Pennsylvania study of the Philadelphia area which is investigating the relationship between migration into the state and mental illness. We are finding that migrants into Pennsylvania from the North have a higher incidence of mental illness than migrants from the South, who in turn have a lower incidence of mental illness than Philadelphia natives. This fact obviously raises many, many questions.

Dr. Nurnberger, in turn, with his conclusion that "The significance of such factors as related to the identification and acceptance of an individual as an institutionalized patient, vary widely with other local circumstances," shows us the limitation of broad classification schemes which obscure important differences, and suggests that intensive study of local practice may be fruitful. He further cautions us against presuming more information than statistical data can provide.

In his careful study Dr. Nurnberger has indeed looked at his tools, his measuring devices, and his concepts. The fact that his regional statistics were in general confirmatory of other studies which reported negative relationships between larger regional institutional admission rate and educational achievement is tempered by his findings of possible differences on a smaller zonal scale between these two variables. Dr. Nurnberger has refined the tool, or the concept by which we measure education, he has perhaps suggested that such broad studies as this can illuminate the next step for investigation, and he may have warned us against over-generalizations.

THE FAMILY AS A POTENTIAL RESOURCE IN THE REHABILITATION OF THE CHRONIC SCHIZOPHRENIC PATIENT : A STUDY OF 60 PATIENTS AND THEIR FAMILIES ¹

ANNE S. EVANS, M.S.,² DEXTER M. BULLARD, JR., M.D.,²
AND MAIDA H. SOLOMON ³

INTRODUCTION

This paper is part of an investigation⁴ of the relative value of drugs on social therapies in the treatment of chronic schizophrenia and was undertaken at the Massachusetts Mental Health Center.⁵

The subjects were 60 inpatients from two Mass. State Hospitals all of whom had to be hospitalized at least 5 years continuously with a diagnosis of schizophrenia.⁶ There could be no diagnosis of organic deterioration or mental deficiency. All patients had to be between the ages of 25 and 50, without any imminent discharge plans. Selection of these patients was made by random sample from 136 patients at the 2 hospitals fulfilling the criteria of selection.

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Massachusetts Mental Health Center, Boston, Mass.

³ Professor Emeritus, Social Economy, Simmons College School of Social Work.

⁴ This investigation was supported by a research grant MY-1690 (C2) from the National Institute of Mental Health; Public Health Service.

⁵ We wish to acknowledge the help of the following staff from the Massachusetts Mental Health Center, Boston, Mass.: George W. Brooks, M.D., Research Director, Drug and Social Therapy Project; Milton Greenblatt, M.D., Assistant Superintendent and Director of Research and Laboratories; Julius Levine, M.D., Research Director, Drug and Social Therapy Project; Esther Cook, Chief, Psychiatric Social Work; Nancy Ogilby, M.S., Chief Psychiatric Social Worker In-Patient Adult Unit; Eva Deykin, M.S., Research Psychiatric Social Worker; Alberto DiMascio, M.S., Statistical Consultant; Virginia Ganick, Typist, Drug and Social Therapy Project.

⁶ The specific diagnoses by the hospital staff were as follows:

Schizophrenic reaction, paranoid type	22
Schizophrenic reaction, catatonic type	13
Schizophrenic reaction, simple type	2
Schizophrenic reaction, hebephrenic type	1
Schizophrenic reaction, chronic undifferentiated type	22
	<hr/>
Total	60

These chronic schizophrenic patients were brought to the Massachusetts Mental Health Center and treated there with tranquilizing drugs and social therapies or social therapies alone for 6 months, with the aim of rehabilitation and discharge(1). A control group remained at the parent hospitals. The improvement in many patients which seemed to warrant discharge did not always result in discharge. The success or failure of plans for discharge was often found to be dependent on the relationship between the chronic schizophrenic patient and his family.

The present report is a descriptive study of the factors that influence the relationship between the chronic schizophrenic patient and his family at the time of transfer. Portions of the data utilize material previously reported(2). Further studies involving the family's role during treatment at the Massachusetts Mental Health Center in the discharge or transfer back to the parent hospital and in the role of the psychiatric social worker at the Center are being reported elsewhere.

This report will present the patient's behavior on the ward and with his family, his social and occupational skills and his financial resources. The family will be examined in detail, including the home situation, the extent of the family's interaction with the patient and the family resources available to the patient.

The families in this study included families of orientation, families of procreation, and collateral relatives of these patients.

METHOD

The patients were transferred to the Massachusetts Mental Health Center beginning November, 1956, at the rate of 1: per week. They remained for a 6-month period unless discharged earlier. The patients remaining at the end of the 6 months returned to their previous hospital unless disposition plans

were in the process of being carried out. During the 6-month period at the Center the first 30 patients were treated with a combination of tranquilizing drugs (chlorpromazine and reserpine) and with intensive social therapies, which included psychotherapy, social casework, contact with students of various disciplines, occupational therapy and a rehabilitation program. The second 30 patients were not treated with drugs but received intensive social therapies alone.

Observations for this report were made on the patients and their families following the patients' transfer to the Center. The patients were interviewed by a psychiatrist and observed by a social psychologist to determine their psychiatric and social disability. Histories of their illnesses were obtained from the hospital records.

The families were interviewed by psychiatric social workers of the inpatient adult unit and research unit. Material included a social diagnostic evaluation of the family situation, and the research staff secured additional information from interviews with the social workers assigned to the cases. Supplementary data concerning the financial resources of the patients and families were obtained from the Department of Mental Health, Commonwealth of Massachusetts.

OBSERVATIONS ON THE PATIENTS AT THE TIME OF TRANSFER

As Richard York(3) points out, "the chronic schizophrenic patient has settled down to a minimum level of activity and social interaction . . . they have slipped into an isolated, anonymous, apathetic condition." These patients were no exception. They were distant and remained by themselves unless urged to join in a social situation. When approached, they were quiet and reserved showing little interest in further contacts, and permeating this isolation was a lack of initiative that hindered any expansion of their social relationships or activities.

Despite their failure to make social contacts, these patients often took care of their personal needs without help from the parent hospital. A majority (52%) maintained an acceptable level of dress and personal

appearance judged by community standards. More than four-fifths (87%) lived on open wards and went to the cafeteria for meals and to other parts of the hospital for activities. One-quarter of the patients made some use of privileges to leave the hospital during the day for walks, job hunting, or trips to the drugstore. Their work records also showed capacities and skills that were utilized in the hospital setting. More than one-quarter (28%) of the patients had a regular job in the hospital, and one-half worked at some daily ward task. All in all, a number of these patients took the major responsibility for their daily life routine and the parent hospital remained a place where basic living necessities were provided, rather than a place where a supervisory or therapeutic program was carried out.

This group of patients took little initiative in their relationships with their families. None was active in phoning, writing, or visiting their families, even patients with full privileges. One patient pretended indifference to his family, only to break down and cry when visited by his brother. When they were visited, or taken out for weekends by their families, the patients were usually docile and, though pleased, did not themselves take steps to continue the family contact. This seemingly indifferent attitude promoted the feeling among relatives and hospital staff that these patients were not ready for further activity and responsibility.

The other resources of these patients reflected the disabling effects of their disease as well as the effects of prolonged hospitalization. Only 1 of the 60 patients had any personal source of income or any savings, as might be expected after 5 or more years of hospitalization. Their job aspirations were limited since few patients had acquired a trade or skilled employment prior to their illness. At the onset of illness, more than one-third (40%) were still in school and only 7 patients had held a skilled job. Added to this, none of the patients held paying jobs during the long period of their hospitalization. Thus, even those with a good hospital adjustment were hampered by poverty, a lack of occupational skill, and little personal initiative.

OBSERVATIONS ON THE FAMILIES

Our material on the 60 families is presented under 3 headings: 1. The family situation; 2. The relationship between the family and the patient, specifically their attitudes toward the patient's illness and his possible release; 3. The family resources available to the patient.

1. The Family Situation: At the time of transfer to the Massachusetts Mental Health Center, four-fifths (48) of the patients had lost at least 1 parent, and one-third (22) had lost both parents. Only 11 patients had married prior to their illness, of whom 7 were legally separated or divorced. There remained only 4 patients with spouses who were available and legally responsible for the patients.

Despite the absence of parents and spouses, nearly all (57) patients had living siblings. This appeared to be a primary resource to the patient. Many siblings, however, lived outside the Metropolitan Boston area. For example, the family of Miss A, a middle-aged female patient, consisted of 2 married sisters, both of whom lived 75 miles away and had young children, making it difficult for them to come to the hospital. Finally, there were 3 patients who had no living relatives.

2. Family Interaction with the Patient: Noteworthy was that most of the families remained interested in the patient even after the prolonged separation. Four-fifths of the 60 patients were visited in the hospital by their families; three-quarters of the families visited regularly either once a week or once a month. The frequency of visits dropped off slightly after the patient had been hospitalized 13 years, yet a majority of these families also visited regularly.

Families' Perception of Illness: The families expressed varying opinions regarding the patient's illness. Twenty-five of the families were "hopeful" of ultimate cure. Three of these families did not believe that the patient was ill. For example, one family stated: "He doesn't really need hospitalization; I don't believe he's really sick—just too timid."

The rest of the families were optimistic as a result of the change of hospital and felt that the patient would be cured. "He's been sick for years. I think he'll get well now that he has been brought here. He'll get more attention." "She seems to be more interested in what is going on around her. I think she's better." "He certainly looks better. He talks to me and I can

TABLE 1
Family Visits in Relation to Length of Patient's Hospitalization

13 and over	6	2	0	4	12
Total	30	14	4	12	60

TABLE 2
Families' Perception of Illness and Its Relation to Length of Hospitalization

LENGTH OF HOSPITALIZATION (IN YEARS)	"HOPEFUL"	DON'T KNOW	"HOPELESS"	TOTAL
5-12.9	22	13	5	40
13 and over	3	4	4	11
Total	25	17	9	51*

* In 9 cases the families' opinions were unknown.

understand what he is saying." Seventeen families could not express a definite opinion regarding prognosis. One family said: "Maybe he can get better here but it will probably take a long time."

Nine families believed that the patient was incurable: "I don't think she'll ever get well." "He's been sick too long—They've tried everything. I don't think he'll ever get better."

If a patient was hospitalized more than 13 years, family attitudes tended to be less favorable about recovery. This feeling on the part of the family is in accord with studies(4) indicating that the prognosis for patients becomes worse as the length of hospitalization increases.

Family Attitudes About Release: A surprisingly large number of families favored release despite the passage of 5 years. More than one-third (23) of the families favored release. They said, "We want him home with us. He's been away too long." "Everybody wants him home." Two-thirds of those families who favored release felt that the patient had a "hopeful" prognosis. Of the 14 families who were ambivalent about release, one-half (6) were "hopeful"

about the illness. These families were "frightened" of the patient but were considering the possibilities of taking him home. They felt that "many new things had happened since the patient was last home," or were fearful of "outbursts." Thirteen families were against release. They either wanted the hospital to guarantee a complete cure or stated, "We have no place for her now."

As one might expect, a belief in cure was associated with a favorable attitude about release. One mother of a single female patient felt that her daughter's illness was curable and was anxious to have her at home. A small group of families opposed release even though "hopeful" about cure and, more significantly, a small group favored release even though feeling "hopeless" about the patients' prognosis. The families who frequently visited the patient were most interested in his discharge. Half of the families who never visited were against release.

The 40 families who favored or were ambivalent about release did not have unrealistic expectations of the patients. One-

* In 6 cases the families' opinions were unknown.

half of the families required only that the patient be able to feed and clothe himself in the home.

3. Available Family Resources: Financial: The families in our study were found to comprise an extremely low income group. Financial resources were discussed with 42 families. One-half of these families made less than \$3000 annually. The median income of these families was \$2500 a year, which is considerably less than the national median family income of \$4971(5) a year.

Twenty-seven families stated that they would be able to assist the patient, 4 were able to assume complete financial responsibility and 23 partial responsibility.

Twenty families could not give any kind

of financial assistance. These families were also found to be unable to support themselves and derived their support from a variety of sources such as distant relatives; S. S. Benefits and Public Welfare.

Living Arrangements: The availability of living arrangements paralleled the families' financial situation. Of the 47 families who discussed living arrangements, a majority (27) stated that they could provide a place for the patient. Twenty-five families had room for the patients at home and 2 offered to subsidize an apartment if the patient was discharged. The remaining 20 families (one-third of the total group) could make no provisions for the patient.

Employment: Virtually no families were

Can make no provision	7	8	3	18	11	9	20
Total	24	14	5	43	36	11	47

Note: The totals represent the number of families whose resources and attitudes were known at the time of transfer.

able to help the patient gain employment. Only one family of the 38 who discussed this question felt they could help the patient get a job. Eleven other families said they would give the patient unpaid employment in the home but the remaining 26 families said that the patient or the hospital would have to assume this responsibility.

Recreational Activities: The family situation appeared more promising regarding recreational activities. This question was discussed with 23 families and 19 had outside social or religious affiliations in which the patient could take part. Four families said that they belonged to no groups or clubs but that they did entertain and would include the patient in their plans.

Regardless of income, one-half of the families were "hopeful" of cure and did not oppose release. Actually both groups tended to favor release even though they were not necessarily optimistic about the patient's prognosis.

The availability of living arrangements was associated with greater optimism and particularly a more favorable attitude toward release. Nearly one-half of the families who could not make provision for the patient opposed release and, more strikingly, 9 of 11 families opposing release could not provide for the patient themselves. In contrast, only 2 of the 25 families who could provide a room or place for the patient opposed release.

DISCUSSION

The present report has examined the family as a resource in the rehabilitation of the chronic schizophrenic patient. Many of these patients had successfully adapted to open ward settings and have fully utilized the available hospital facilities. Inherent in the nature of the patients' disability was a lack of initiative which prevented them from undertaking contact themselves with the community. We wondered whether this hospital level of functioning could not be extended to an increased interaction with the community. We found that the family is the primary resource available to the patient in the community.

A striking finding of this study is that

families continued to visit even after the patient had been hospitalized more than 5 years. When parents could no longer visit due to old age, illness or death, the siblings assumed this responsibility. One should not underestimate the strength of family ties even after prolonged separation. The nature of this bond and to what extent it involves affection, guilt and other feelings needs further investigation. Contrary to our expectations, the patient's age was not related to the frequency of family visits. One reason for this may be the limited age range of our sample, 25 to 50 years. The sex of the patient did not affect the number of family visits. An interesting sidelight was that casework interview material revealed that families expressed more fear of possible aggressive actions of the male patients than of the female patients.

Even after long-term illness the family for the most part continued to maintain a positive attitude toward the patient's illness and optimism about release. The family's minimal expectations of performance, in the event of release, was found to be in keeping with the patient's individual capacities. They realistically expected no more of the patient at home than they had observed in the ward setting. The authors believe that the hospital's expectations for discharge of the chronic patient are often higher than the family's tolerance for his disability. Under these circumstances, the hospital may not utilize the family's positive feelings as often as it could. The fact that more families of male patients expected them to provide financial assistance suggests a different approach in their rehabilitation. Rehabilitation of female patients should be oriented around a home situation and rehabilitation of male patients should include specific help toward a job situation.

The marked limitation of family resources suggests that some families cannot afford to have the patient at home. Economic necessity then becomes an important factor in disposition planning which must be considered together with the patient's clinical condition. Although differences in family attitudes did not appear to be related to their economic condition,

further help may be needed for those families with low income in order that they do not become terribly oppressed as a result of accepting the patient into their home.

These problems may be met in several ways. The hospital needs more psychiatric social workers to stimulate and assist the patients who have reached the stalemate of a successful open ward adjustment. Social casework with the family may enable them to deal more effectively with the problems of chronic schizophrenia. The worker can assist the family to make better use of the existing community facilities. There is a need for expanded community resources geared to the patient's increased interaction with the community. These might include greater financial aid to the family, increased use of family care programs(6), more half-way houses(7), and sheltered workshops. Even more important is the need for a positive attitude toward the possibilities of increased social effectiveness of the chronic patient by the psychiatric social worker, the hospital staff, social workers in the community, and the community itself.

SUMMARY

Sixty families of chronic schizophrenic patients undergoing treatment with drugs and social therapies were studied to determine their potential role in the patients' rehabilitation and discharge.

Many of these families maintained an active interest in the patients, expressed in continuing visits to the hospital. Their attitude toward the patient's illness was optimistic and many families favored discharge. Their expectations were realistic and in accord with the patients' capacities. Their ability to help the patient was compromised by a low annual income, insufficient room at home for another family member, and inability to help the patient find a job. The importance of the increased use of the psychiatric social worker and of additional community resources was emphasized.

DISCUSSIONS

HERMAN DENBER, M.D. (New York, N. Y.). —It is difficult to make critical remarks about a paper with which one is in agreement on most points. Mrs. Evans and her collaborators have studied a problem of unusual importance to those interested in rehabilitation of the chronically ill; a problem becoming more and more urgent with large scale use of chemotherapy reclaiming many long-term residents of mental hospitals.

There is a small question concerning methodology: on page 2 it is stated that the report refers to the factors operating "at the time of transfer," while on the next page it states that "observations . . . were made . . . following the patients' transfer to the Massachusetts Mental Health Center." Further along it is stated that "this report will present the patients' behavior on the ward." It would be of interest to know exactly when and where these observations were really made.

In examining the description of the patient sample, one is struck with the fact that this is a prognostically hopeful group with 87% having been in open wards, and 25% being able to leave the hospital for various parts of the day. It is difficult to reconcile this active "motor" life with seemingly indifferent emotional attitudes to relatives: inertia in schizophrenia is usually all pervasive.

Very little can be added to the observations, except to say that a rather high percentage of families still maintained a positive feeling to their relatives in spite of the duration of hospitalization. This has not been our finding. Fully half of 20 chronic patients on the ward have had no visitors at all or only a rare relative or friend.

It is not unusual to find families utterly opposed to a patient's release. The latter has been written off, so to speak; their place in the household sequestered and belongings disposed of. The proposal of returning a patient to this environment is usually greeted by the family with a panic reaction. Yet it is surprising how intensive casework can occasionally convert this attitude to one of acceptance.

The authors have found that the family is the primary resource available to the patient in the community. While this is theoretically true, we must view such a hypothesis with care. If chronic patients are to be discharged from the hospital, an intensive multi-disciplinary project must be set into motion in which the family plays but a small role. In our setting in Manhattan State Hospital, where the therapeutic community project has aimed at discharging long-term patients, the family was found to be one of the weak links in the community and we have been dismayed often by their attitude. As a matter of fact, the psychopathological findings in families of long hospitalized patients are startling. This may be a function of case material, since our patients form a heterogeneous group.

It is stated that "the marked limitation of family resources suggests that some families cannot afford to have the patients at home." I think this is a screen for rejection of the patient. While we have occasionally found this to be true, more often it was used as a pretext when the patient was not wanted. It is usual that adequate arrangements be made for the patient's maintenance before separation from the hospital. Intensive rehabilitation procedures should make male patients (and female patients as well) ready for gainful occupation in the community. Why then must "further help be needed for those families with low income in order that they do not become terribly oppressed as a result of accepting the patient into their house?"

While "the hospital needs more psychiatric social workers," and "social casework with the family enable them to deal more effectively with the problem of chronic schizophrenia," this is not enough. Again, the accent here is placed in one small area when we must look at the total picture of which these are but small components.

What seems to be unsaid in this paper is the magnitude of the social problem confronting psychiatry with the thousands of chronically ill long-term residents of mental hospitals, many forgotten or abandoned by their families, and others without family ties at all. We are, perhaps, based on our own case material, less

optimistic than the authors about the potential of the patient's family in the rehabilitative process. But we would strongly and vehemently support their thesis for more effective casework with families during the patient's hospitalization and afterwards.

The low socio-economic status, low I.Q., and poor job training, *etc.*, all hinder effective mobilization of the chronic patient. The defective conceptualization of family ties in many layers of our 20th century American culture does not facilitate the stated task. For instance, it is doubtful if "greater financial aid to the family" will achieve the aims outlined by the authors. What is needed is an entirely new approach to the social and economic problems of our patients; this falls within the province of the political scientists, the sociologists and the economists.

The psychiatric social worker will render an optimum service to psychiatry by complete integration into the therapeutic force operating in the direction of the patient's health. Mrs. Evans and her co-workers deserve our thanks for highlighting a significant problem area. The positive attitudes they have formulated are worthy of emulation.

RUTH I. KNEE (Bethesda, Md.).—The current interest in the rehabilitation of chronically ill patients, in discharging them from mental hospitals, and in finding some way for them to live in the community, has focused renewed interest in, and placed new significance upon, the patient's family. It has also meant a different approach to the family on the part of those who are responsible for the care and treatment of the patient, including the social worker. Traditionally, the social worker has been described as the link between the patient, the hospital, the family, and the community. There is something that is much more promising and challenging about using this intermediate position to find the positives in the family and the community and to make them available to the patient and the hospital, than there was when it appeared that the only, or major, use of the social worker was to make detailed studies in how the family had caused or contributed to the patient's illness. Her helping relationship with the family was largely used for the purposes of "interpreting the need for hospitalization and helping them to accept it."

The study reported is not an attempt to report on what was done in a few instances of successful casework which enabled families to help their ill members. Rather it is an examination of certain of the family resources in a

selected group of chronic schizophrenic patients who had been hospitalized for a number of years. It gives a cross section view of the attitudes of family members and the possible resources for rehabilitation that families offer to patients at one point in time. It does not attempt to tell us how these attitudes had come into being, what influence they had had upon the patient's illness and hospitalization in the first place, nor what happened to the patient as a result of the knowledge of the potential resources offered by the family. We are giving here a summary of the general kinds of possible contributions that the families of a group of long-term schizophrenic patients could make to their discharge and rehabilitation. These summarized data offer certain surprises and contradictions to some of the stereotyped ideas we might have about families. In spite of periods of hospitalization lasting many years, these patients were still visited by some member of their family. They had not been completely "forgotten." The families were accessible for interviews with the social worker and cooperated in the interviews and were still taking the initiative in keeping in touch with the patient. However, during the intervening years since hospitalization, there had been major shifts in family composition with death of one or both parents or divorce. Most of the family members considered the responsible relatives were siblings. Thus for most of the patients the concept of family did not mean the family of orientation or procreation.

Another surprise might be that in spite of the long hospitalization, a rather high proportion of the family members were hopeful of the ultimate cure and gave some indication that they would be willing to have the patient live with them. It would have been interesting to have had a similar study made at some time prior to the patient's transfer into the study group and of the control group. One would see how much families' attitudes of hope were related to the fact that the patient was receiving more intensive treatment than he probably had at any time before during his hospital career. It is also interesting to com-

pare these attitudes with those expressed during a study made of relatives' attitudes at a Veterans Administration Hospital—"Relatives' Attitudes and Mental Hospitalization." Most of the relatives interviewed in this VA study had a more pessimistic view about the patient's illness and were more reluctant to consider having the patient live with them. Perhaps there is a further clue to the reason for this contrast in the statement of the authors that relatives were much more concerned with the aggressive behavior of males than with females.

There were a number of areas in which the families appeared to offer minimal resources. The lack of financial resources of almost half of the families would make very difficult any arrangements to have the patient live with the family following hospitalization. The State was spending almost as much to give the patient custodial care as the family earned in a year. The lack of appropriate living space for the patient also minimized the families' potential as a resource. We wonder whether there had been changes in the family's economic status and employment level during the period of the patient's hospitalization or had this remained static. With those families having adequate financial means and living space, one wonders what kind of stimulation there would be in the daily living with a widowed parent as the established family of a sibling. It gives clues as to which families might be selected for more intensive help in planning.

This study illustrates that even after long-term illness the family continues to maintain some ties with the patient and looks to eventual discharge. However, the crucial test must still be what real support, either emotional or financial, can a sister or a brother give to a patient following his discharge from a hospital. In addition, there is strong evidence for the need of a variety of kinds of community supports, such as public assistance, living arrangements, social therapeutic clubs, that can provide for the patient the kind of help that the family is unable to give.

LOS ANGELES SUICIDE PREVENTION CENTER¹

ROBERT E. LITMAN, M.D.,² EDWIN S. SHNEIDMAN, Ph.D.,³
AND NORMAN L. FARBEROW, Ph.D.³

Suicide and suicide prevention provide major problems for clinical psychiatry and community psychiatry. Considering their importance, these problems have received relatively little organized study and attention. Although there exist in the United States and Europe several worthwhile anti-suicide services, conducted by philanthropic and religious groups, there have been no reports in English of comprehensive and systematic suicide prevention projects.

The purpose of this paper is to report progress in the development of a suicide prevention center (S.P.C.), staffed by psychiatrists, psychologists, and social workers. This work is being conducted in Los Angeles, and administered through the University of Southern California.

In addition to the primary goal of saving lives, which is shared with other anti-suicide organizations, the Los Angeles Suicide Prevention Center has 3 additional, unique goals: (a) to demonstrate the relationship between an S.P.C. and other community, mental health agencies; (b) to serve as a pilot project for other communities interested in establishing a suicide prevention program; and (c) to collect hitherto unobtainable, research data on the etiology, meaning, and prevention of self-destruction.

The principal activities of the S.P.C. are: 1. Providing intensive psychiatric, psychology, and sociologic investigation of some suicidal persons, leading to an evaluation of the person in his situation, with emphasis on the degree of suicidal danger; 2. Making appropriate therapeutic recommendations and referrals to these persons and obtaining periodic follow-up reports to observe the

progress of the cases; 3. Consulting with community agencies and practitioners confronted with special problems of suicide and exploring these special problems; 4. Collecting and analyzing data, leading to increased understanding of suicide and ideas for additional suicide prevention measures. These therapeutic, community oriented, and research activities proceed concurrently and harmoniously.

Our current strategy for suicide prevention work is derived from recent studies which showed that the great majority of persons who commit suicide make their intentions known in advance through suicidal threats, suicidal attempts or certain behavior patterns (such as the depressive syndrome or sudden increase in alcohol and barbiturate consumption). We have, then, a rather large group of potentially suicidal persons, which contains within it, as a relatively small sub-group, the majority of committed suicides. Very little is now known about the total number, range, and characteristics of the population of potentially suicidal persons. We are using 3 methods to obtain these much needed data: (a) surveys of the community with questionnaire and interview techniques; (b) abstracting large numbers of charts from emergency hospitals, general hospitals and psychiatric hospitals; (c) the gradual accumulation of detailed case material at the S.P.C. In addition, we have collected information on suicidal victims through interviews with surviving relatives, friends, physicians, and other informants. We plan eventually to compare 4 groups: committed suicides, suicide attempts, suicide threats, and non-suicidal persons.

For example, we made a survey of all Los Angeles physicians for their experience with suicide attempts, receiving a gratifying 80% response. From these responses and reviews of the charts of several hospitals, we obtained identifying data (sex, age, race, marital status, occupation, location in the city, method, time, and outcome of attempt) for 2600 suicide attempts, representing a

³Co-Project Directors; this work has been conducted under a 5-year U. S. Public Health Project Grant No. OM-128.

sizeable fraction of the total (estimated conservatively to be 6,000 to 7,000) for Los Angeles in 1957. In selecting suicide attempt cases for intensive study, the S.P.C. has been attempting to duplicate proportionately the characteristics of the total group of suicide attempts. Many of our cases were seen in hospitals soon after a self-injury. Others came from a variety of referral sources, such as physicians, judges, social work agencies, and there have been a number of self-referrals.

At the S.P.C., case histories are obtained from patients and significant relatives and friends by the professional staff members, and a battery of psychological tests is administered. Much of the information obtained is coded and punched on cards for future analysis. We have been particularly interested in evaluating the degree of suicide danger through such indicators as the psychiatric diagnosis, the effects the patient's communication has on others, the meaning to the patient of his self-destructive behavior, the actual lethality of his behavior, the manifest anger, the self-image, the unconscious masochism, positive and negative reactions to therapy and so on. Possibly, with the aid of computing machines, we will be able to construct formulae for reducing these diverse and complex data to a few comprehensive indices of suicidal danger.

Until such formulations are developed, a discussion of this crucial problem, the assessment of suicidal potential, should be liberally spiced with case illustrations, which space limitations preclude. What follows, therefore, are a few highly condensed extracts from our clinical experiences.

Many persons who made suicide attempts or threats appeared to us to have a very low potentiality for suicide. In this group the patients were immature, passive-dependent, passive-aggressive, self-dramatizing individuals who simulated a suicidal mode of action in order to gain a point or manipulate a key person. The actions were impulsive, usually occurred in close proximity to other persons, often when anger would have been appropriate, and could have been a threat to life only by accident or miscalculation. Such persons usually have a record of chronic instability in their per-

sonal relationships and frequently can profit to some extent by family counseling and casework in social agencies. Then, the role of the S.P.C. has been to reassure the agency against the danger of suicide and act in the capacity of a consultant.

We encountered a number of persons whose suicide potential was moderate in that the risk of death depended upon the outcome of a very close, disturbed, ambivalent, interpersonal relationship. These mostly involved spouses or lovers but also included homosexual partnerships and parent-child combinations. In fantasies, these persons wanted to die but also wanted to be rescued and live. In suicide attempts, they often endangered their lives severely but also made provisions for being rescued, as if their danger was an ordeal or a trial of love or a gamble with death. We have been impressed by the durability of these ambivalent ties between people and how they resist change. Often both persons in the dyad are potentially suicidal. If such ambivalent but symbiotic interpersonal bonds are broken too abruptly, self-destructive actions can be anticipated.

High suicide potentiality was associated especially with severe depression, restless schizophrenia, and alcoholics who had exhausted their emotional resources. Suicide in such persons is seldom a matter of sudden impulse, and thoughts of suicide appear persistently in their interviews and psychological tests. The danger here is that the patient may be overlooked and returned to the community even after a suicide attempt. When the suicidal danger is evaluated as high, we have found no substitute for the safety and other therapeutic advantages of a psychiatric ward.

Resistance to the idea of psychiatric hospitalization is extremely common, both in patients and their families. We found that the sooner we interviewed a patient and his family, during a time of suicidal crisis and anxiety, the better, and we had to accustom ourselves to evaluating patients quickly and making emergency dispositions. The attitude of the relatives and family was often a decisive factor in the decision whether to hospitalize a patient or recommend ambulatory therapy. When there was no family or friends available, we have occasionally used

volunteer assistants to accompany a suicidal person to the hospital.

As we receive more and more telephone inquiries, the need for a 24-hour emergency psychiatric service emerged, and we have considered possible ways to institute such a program. So far, we have been able to use the panels of physicians set up by the medical associations who are available for emergency calls. During the first year of activity, the S.P.C. was in touch with well over 50 community agencies and resources in its efforts to help patients. We have received from other agencies numerous requests for information and brief consultation and acted as a referral service for many cases we did not see ourselves. We have been asked for consultation opinions on such issues as: what should a telephone operator or intake social worker say to persons who threaten suicide over the phone? How should a suicide occurring on a psychiatric ward be handled with the other patients and medical personnel? How can we predict when recovering suicidal patients are ready for discharge? We are working with the Los Angeles police department in a project to determine how many persons who committed suicide had previous contacts with the police. The Superior Court in charge of commitments has asked us to evaluate certain prospective commitment cases whose status was obscure.

One aspect of our work with community agencies deserves special mention. Dr. Theodore Curphey, the Los Angeles Coroner, deputized members of our project to assist him in investigating a large number of cases in which the mode of death was not clearly indicated by the physical evidence and routine police reports. He noted that only about two-thirds of the suicide certifications made in his office were based on absolutely unequivocal evidence and about one-third demanded some sort of psychological inference as to the intention of the victim. Similarly, there was another group of cases in which a certification of suicide might very well have been made but psychological inference led to a presumptive diagnosis of accident. He felt that psychiatrists and clinical psychologists could add a new dimension to the diagnosis of intention even in a dead person. Information from our

interviews with relatives, physicians, friends and other informants, reviewed with the Coroner at what he calls "psychological autopsies" did indeed clarify the diagnosis in a number of cases.

Our reports confirmed previous observations that many accidents and homicides are closely related to suicide. We learned that a systematic bias on the part of the Coroner would substantially affect suicide statistics for any given community; that certain masochistic perversions can and do lead to death by asphyxiation or hanging; that most persons who play Russian roulette cheat; that persons who are taking large amounts of barbiturates over any extended period of time are living on the very edge of death and often slip over without quite meaning to; and that interviews which were primarily investigative often had secondary therapeutic benefits. Survivors of the deceased were able to express feelings and obtain information which reduced guilt and helped them formulate plans for solving problems, for example about the children of a parent who committed suicide. Noting this, the Coroner began referring distraught survivors of suicide victims to us for supportive interviews even when the mode of death was not in doubt.

CONCLUSION

Suicidal reactions represent a complicated synthesis of mental illness and interpersonal or social-living problems. Many potentially suicidal persons can be greatly helped by appropriate psychiatric treatment. Often pre-suicidal behavior is associated with strong defensive efforts (in patient and relatives) to deny the problems and avoid facing the illness. Opportunities to circumvent the resistance should be seized whenever possible.

Some benefits of a Suicide Prevention Center are:

1. Some pre-suicidal persons get appropriate treatment who might not otherwise get treatment.
2. Much needed data, especially longitudinal studies of the lives of pre-suicidal persons, are collected and analyzed.
3. The S.P.C. facilitates the functioning of a number of different agencies and com-

munity resources where they are concerned with suicide, leading to smoother handling of pre-suicidal persons.

4. The S.P.C. helps provide educational information for police, physicians, judges and others in a position to recognize pre-suicidal persons.

5. Proper publicity might help overcome the popular prejudice against psychiatric hospitalization.

6. The S.P.C. offers an opportunity for experimental activities such as psychiatric emergency call service and the use of supervised volunteers in emergency situations.

Finally, it should be said that there is

more to suicide than mental illness. In a sense, self-destruction reflects the relationship of the individual to his community and his civilization. It may be that a certain minimal level or rate of suicide is "built in" to our competitive culture, part of the price we pay for our prized individual freedom to dispose of our lives as we wish. As the Suicide Prevention Center develops we hope to increase our knowledge of suicide, sharpen our diagnostic accuracy and contribute answers to some of the questions we have raised, but as far as we can see into the future, suicide and suicide prevention will continue to present new problems.

THE EFFECTIVENESS OF PSYCHOTHERAPY ALONE AND IN CONJUNCTION WITH PERPHENAZINE OR PLACEBO IN THE TREATMENT OF NEUROTIC AND HYPERKINETIC CHILDREN¹

LEON EISENBERG, M.D., ANITA GILBERT, M.S.S., LEON CYTRYN, M.D.,
AND PETER A. MOLLING, M.D.²

INTRODUCTION

This paper will report the preliminary findings of a study comparing the effectiveness of three short-term treatment schedules, consisting of (a) psychotherapy alone, (b) placebo plus psychotherapy and (c) perphenazine plus psychotherapy, upon the response of each of 2 patient groups, designated as (I) neurotic and (II) hyperkinetic. The present study is one of a series³ designed to weigh the effectiveness of pharmacologic and psychologic factors in treatment of disturbed children. The plan of this experiment and the significance of its findings can best be understood in the context of a brief summary of the results obtained in a previous investigation.

PREVIOUS FINDINGS

By a double-blind study design, we contrasted the effectiveness of meprobamate (800-1600 mg.), prochlorperazine (20-40 mg.) and placebo in the treatment of disturbed children who received concurrent brief psychotherapy (1). Tables 1 to 3, modified from the original paper, summarize the principal findings.

TABLE 1—1959

Agent	Improvement		Total
	Significant	Mild or None	
Meprobamate	8	7	15
Prochlorperazine	7	12	19
Placebo	14	6	20
Total	29	25	54

Table 1 indicates the clinical outcome of patients on each of the 3 medication sched-

ules. It is clear that the results provide no evidence for superiority of either drug to placebo. Indeed, it appears that patients on prochlorperazine did less well than those on placebo. This finding may correlate with the 30% incidence of side effects from prochlorperazine, which was twice that from meprobamate and four times that associated with placebo.

Since we had anticipated that patient response might be a function of psychiatric reaction type (2), we examined the response within each of the major diagnostic categories we employed. The diagnosis neurotic was made in those cases in which the manifestations of, or defenses against, anxiety were predominant, in accordance with APA nomenclature. It should be emphasized that some of these children might have been classified under the rubric: adjustment reaction of childhood, neurotic traits. The duration of the symptoms—6 months to 2 years—made it difficult to consider these as transient situational reactions, although this appears to be common practice in mental hygiene clinics (3).

Children who were overactive, distractible, non-conforming and disturbing to others, but who showed little or no anxiety, were classified as hyperkinetic. It should be noted that children with sociopathic behavior were *not* included in this category.⁴ Table 2 reveals the similarity of the response within each of the diagnostic categories to each of 3 treatment schedules.

In view of the lack of evidence for specific therapeutic action by either of the drugs, it appeared justified to sum the treatment subgroups in order to examine diagnostic category as a variable relevant to outcome. When this was done, the marked difference between the response of neurotic and hyperkinetic children was revealed, with 70% of

Prochlorperazine	4	7	11
Placebo	6	5	11

the former and only 40% of the latter showing significant improvement. The chi square for Table 3 is 4.34, corresponding to a probability value of less than 0.05.

TABLE 3—1959
Response as a Function of Diagnosis

Neurotic	15	6	21
Hyperkinetic	14	19	33
Total	29	25	54
$\chi^2=4.34$		$p<0.05$	

The lack of an untreated control group precludes any conclusion as to whether the response was "spontaneous" or "therapeutic." But there is evidence of a relationship between diagnosis and outcome and none for a pharmacotherapeutic action of either of the drugs studied.

It was of interest that the favorable response of the neurotic cases was maintained at re-evaluation 1 month and again 7 months after the termination of treatment. Preliminary results (unpublished) from an 18-month follow-up study of the original patients show maintenance of improvement in the neurotic group but a gradual loss of even the lesser gains obtained by the hyperkinetic group.

It therefore seemed to us to be of interest to examine the following questions: Could the finding of a predictable difference in outcome as a function of diagnosis be confirmed? Was the apparent therapeutic response dependent upon placebo administration or could it be obtained with psychotherapy alone? Would a new agent, perphenazine, prove to be more effective than placebo?

METHOD

In order to investigate these questions, we employed the following procedure. Patients were assigned randomly to one of 3 treatment schedules: (a) psychotherapy without medication (b) psychotherapy plus placebo (c) psychotherapy plus perphenazine (8-16 mg.). It was not possible to conceal from the therapists the patients not receiving medication, but they did not know which patients were on placebo and which on perphenazine. For those cases who received "medication," the number of capsules prescribed was increased by 50% and later by 100% if no improvement was noted at the 1 week and 3 week examinations, respectively.

The treatment program, described in detail in the original publication(1), consisted of 5 sessions: an initial 60 to 90 minute evaluation by a social worker who saw one or both parents and a simultaneous interview with the child by a psychiatrist, plus 4 half-hour treatment sessions for both parent and child at 1, 3, 7 and 11 weeks after intake. After the 7th week session, all medication was discontinued in order to permit a final evaluation of behavior without medication.

Improvement scores were based upon the mother's report to the social worker, an independent assessment obtained from the school, and the psychiatrist's impression from observation of the child. In our previous study, we had found significant correlations between each pair of these 3 scores. In the present study, with a more scrupulous effort to have the psychiatrist make his evaluation without knowledge of the mother's or the school's report, the psychiatrist's score was found to be at variance with the home and school scores, whereas the home and school scores remained highly correlated. The final decision as to improvement was made jointly by the psychiatrist and the social worker from a review of the available information from home, school and clinic, with greater weight given to home and school information than the impression gained from the clinical interview.

Improvement was scored as "significant" when symptomatic change was sufficient to permit the child to effect a more satisfying interpersonal adjustment and as "mild"

when amelioration of symptoms occurred without a meaningful change in adjustment. For clarity of presentation, the category of significant improvement has been contrasted with a combined category representing both mild improvement and no change. This, in essence, imposes a demand for unequivocal change before a patient is classified as improved.

As an independent check on the prognostic implication of the diagnostic categories, 17 neurotic and 15 hyperkinetic cases, treated at the parent clinic by conventional outpatient psychotherapy during the same time of the year (2) as the experimental patients, were randomly selected from the files of the Children's Psychiatric Service. Assignment to diagnostic category was based upon a study of the initial history and examination. After this determination had been made, the treatment interviews were examined at intervals corresponding to those employed in the experimental study in order to determine improvement.

RESULTS

The data were first examined by diagnostic category. Table 4 indicates the response distribution for the experimental group at the 7th week. Two-thirds of the neurotic cases as opposed to one-third of the hyperkinetic cases demonstrated significant improvement, a difference significant at better than the 0.05 level of confidence.

TABLE 4—1960
Response as a Function of Diagnosis

Diagnostic Category	Improvement		Total
	Significant	Mild or None	
Neurotic	21	12	33
Hyperkinetic	8	15	23
Total	29	27	56
$\chi^2=4.73$		$p<0.05$	

A separate analysis of the record search of the clinic treatment cases, in Table 5, reveals similar but even sharper findings: 70% improvement among neurotic versus 15% among hyperkinetic cases.

Both the experimental and the clinic cases confirm our hypothesis that the diagnostic differentiation between "neurotic" and "hyperkinetic" is a meaningful predictor of out-

come in patients receiving brief outpatient treatment.

In order to assess the effect of placebo administration on the impact of psychotherapy, Table 6 lists outcome for the experimental group by diagnosis and by treatment schedule. There do not appear to be any notable differences between the 2 treatment schedules, although the numbers are small and the finding cannot be considered as firmly established for this reason.

TABLE 6—1960
Response as a Function of Diagnosis and
of Treatment in Experimental Subjects

Diagnostic Category Agent	Improvement		Total
	Significant	Mild or None	
Neurotic			
1. Psychotherapy Alone	8	5	13
2. Psychotherapy plus placebo	8	4	12
Hyperkinetic			
1. Psychotherapy Alone	1	6	7
2. Psychotherapy plus placebo	1	4	5

The homogeneity of the response rates in these 2 non-drug groups appeared to warrant combining them into one category for contrast with the drug group in Table 7.

For the neurotic patients, perphenazine appears to offer no advantage over the psychotherapy or placebo schedule. It should be borne in mind, however, that the improvement rate in the neurotic patients is so near ceiling in the placebo comparison groups that a drug would indeed have to be highly potent for its effect to be manifested.

For the hyperkinetic patients, however, there does appear to be a suggestion of

TABLE 7—1960

2. Psychotherapy with or without Placebo	2	10	12

benefit from perphenazine beyond the placebo effect. A current double-blind study of perphenazine and matched placebo in hyperkinetic patients should serve to provide more definite information.⁵

TOXIC REACTIONS

Complaints about side effects were noted in 6 of the 19 patients on perphenazine and in 2 of the 17 on placebo. Seven of the 8 complaints were limited to drowsiness which remitted without change in dosage. The one toxic reaction of consequence occurred in a hyperkinetic child on perphenazine; he developed torticollis and marked drowsiness, both of which disappeared when the dose was reduced from 8 mg. to 4 mg. per day.

DISCUSSION

In two experimental investigations and one retrospective study, a significant difference has been demonstrated in the clinical response of children with "hyperkinetic" and "neurotic" reaction patterns. The regularity of the finding is emphasized in Table 8 in which the clinical results from the 3 studies are summarized. With the possible exception of the hyperkinetic service patients, about whom we shall comment in a

⁵ Thus far (Jan. 1961), 39 additional hyperkinetic subjects, 19 on perphenazine and 20 on placebo, have been processed in this new study. An analysis of the results indicates that the "suggestive" findings noted above were a function of random variation; when the 39 new patients are added to the 23 reported in this paper, the outcome of the placebo series is identical with that of the perphenazine series. These findings will be reported in greater detail (13).

later paragraph, the mean improvement scores for each reaction type are strikingly consistent from one study to another.

TABLE 8
Three Studies Contrasted

Diagnosis & Study	Improvement Category		Improvement Mean-Score
	Significant	Mild or None	
Neurotic—1959	16	5	1.7
Neurotic—1960	21	12	1.5
Neurotic—C.P.S.	12	5	1.6
Hyperkinetic—1959	14	19	1.1
Hyperkinetic—1960	8	15	1.1
Hyperkinetic—C.P.S.	2	13	0.5

If we combine the results of the three studies, a step that would appear permissible in view of their similarity, it can be seen in Table 9 that the 2 syndromes behave in almost diametrically opposed fashion. The chi square for the table is 16.78, which is highly significant ($p < 0.001$).

TABLE 9
Three Studies Combined

Diagnostic Category	Improvement		Total
	Significant	Mild or None	
All Neurotic Cases	48	23	71
All Hyperkinetic Cases	24	47	71
Total	72	70	142
$\chi^2 = 16.78$		$p < 0.001$	

It might be contended that the magnitude of the difference, though great, is simply an expression of the investigators' anticipations which unwittingly colored their evaluations of change. Three considerations militate against this possibility. First, we did not anticipate this sharp difference in outcome at the time of the first study, whose findings became evident only when the results were tabulated. Second, the several residents who treated the service cases were not familiar with the hypothesis. Third, the difference in outcome was clearly evident in the school teachers' ratings of both experimental groups.

The predictable relationship between outcome and reaction type emphasizes the importance of diagnosis (4). It may well be that one factor in the disenchanting results regularly obtained in efforts to evaluate outpatient treatment (5) arises from the failure

to contrast treated and untreated cases within each diagnostic category rather than for a heterogeneous assemblage of patients whose initial diagnostic characteristics are not segregated (6). If our findings are valid, then it is clear that mere differences in the proportions of hyperkinetic and neurotic cases assigned to treatments x, y and z could result in entirely spurious evidence in favor of one over another.

The poorer outcome of the hyperkinetic children treated as service cases as compared with those in the experimental study may, of course, be an adventitious difference. However, a study of the drop out rates is instructive in this regard. As might be anticipated, the drop out rate for neurotic cases did not exceed 5% in any group. However, the rate of drop outs for the hyperkinetic cases by the third month was 60% for the service cases whereas it was less than 10% for both experimental groups. It is our clinical impression that this difference resulted from the emphasis on time-limited and goal-limited therapy in the experimental study as contrasted with the conventional open-ended approach. This suggests the unsuitability of the model of the treatment of neurosis in the approach to the treatment of hyperkinetic syndromes.

The indifferent response of hyperkinetic children to short-term psychotherapy with or without accompanying placebo may reflect the presence in this group of a core of cases with an organic syndrome of "constitutional" or traumatic etiology (7). It is significant in this regard that Pasamanick and his co-workers (8) have found a higher incidence of complications of pregnancy and parturition in the birth records of children with behavior disorders, a finding that was most striking for those cases classified as "hyperactive, confused, and disorganized." Moreover, O'Neal and Robbins (9) found a much higher rate of adult psychiatric disability in the later careers of children with aggressive behavior disorders than of neurotic children, although their categories and ours do not correspond completely.

It would appear that hyperkinetic children are a population at risk for psychiatric disability and yet are less likely to be taken on as treatment cases by most child psychiatry clinics because of their unsuitability for

the preferred mode of treatment; namely, psychotherapy (10). This highlights the importance of research with a variety of treatment methods, among which pharmacotherapy would appear to have a high priority. Rather than contenting ourselves with treating what we know how to treat but may be less in need of treatment, we should search for methods of reaching those who seem refractory to present techniques and constitute a reservoir of psychopathology (10).

Our results with the neurotic reaction patterns are consistent with the general clinical impression of the effectiveness of outpatient therapy for psychoneurosis. We are currently investigating measures to provide a comparable untreated control group of neurotic patients in order to assess the extent to which spontaneous remission of symptoms may account for these findings. But, at the least, the good symptomatic result from short-term therapy, sustained at re-evaluations 6 and 18 months after termination of treatment, suggests the desirability of a short-term focus in mental hygiene clinics in order to reach a larger number of patients than is possible when long-term treatment pre-empts scarce professional time (11).

Indeed, it is conceivable that long-term therapy for all but severe psychiatric disorders may increase disability by fostering dependency and by permitting, if not encouraging, the patient to focus on pathology. Other studies have indicated that a time limit hastens the therapeutic process (12), perhaps by necessitating an emphasis on the mobilization of assets. In essence, the patient and his family are being encouraged to assume responsibility, and are being reassured as to their competence to do so, by the emphasis on time-limited treatment.

The prompt and usually satisfactory response of neurotic cases to brief psychotherapy leaves little room for any but the most remarkable drug to demonstrate its effects. Whether drugs or placebo alone might be effective where even brief psychotherapy is unavailable is a question that deserves exploration although it is methodologically difficult to exclude the impact of the doctor-patient relationship. On the other hand, it is clear that the unsatisfactory results with the hyperkinetic behavior disorders necessitate

a search for pharmacologic and other therapeutic agents. We are in the process of extending our current suggestive findings with perphenazine by pursuing its use in a larger series of cases and are inaugurating a study of agents with contrasting chemical properties.

SUMMARY

Pediatric patients with neurotic and hyperkinetic reaction patterns have been treated experimentally on one of 3 schedules: (a) brief psychotherapy, (b) brief psychotherapy plus placebo, (c) brief psychotherapy plus perphenazine. Analysis of the clinical response rates has led us to the following conclusions:

1. Children with neurotic symptomatology show a prompt and enduring response to a brief program of psychotherapy at a level of improvement (60-70%) that is significantly greater than that attained by children with hyperkinetic syndromes (15-40%).

2. No evidence was obtained for any enhancement of the response to brief psychotherapy from the addition of placebo medication.

3. We were unable to demonstrate a significant difference between response to placebo and to perphenazine when administered concomitantly with psychotherapy.

The implications of these findings have been discussed.

A RESEARCH MODEL FOR THE EVALUATION OF THE EFFECT OF PSYCHOPHARMACOLOGICAL AGENTS¹

DAVID W. McCREIGHT,² M.D., NOLAN D. C. LEWIS, M.D.,
MORRIS REBY, M.D., AND JOSEPH M. TOBIN, M.D.³

PURPOSE OF STUDY

The purpose of this study was to determine the therapeutic effectiveness of a new psychopharmacologic agent, a pipiridyl phenothiazine, No. 2445, in the treatment of chronic schizophrenic patients who exhibit various degrees of withdrawn behavior. The study was also designed to demonstrate the feasibility of collaboration between a central research bureau and the service staff of a state hospital.

METHOD OF STUDY

The series included 47 patients, 23 males and 24 females, with a clearly established diagnosis of schizophrenia. Their ages ranged from 24 to 68 years. Chronicity, in terms of hospital residence, ranged from 2 years 3 months to 38 years 6 months. This biased sample was divided into 2 subgroups of 16 patients each, 8 males and 8 females, and one subgroup of 15 patients, 7 males and 8 females. (This third group, diagnosed as Group I, or mildly withdrawn, had its 8th male drop out at the beginning of the study because of persistent weight loss during the baseline evaluation). The 3 groups represented degrees of withdrawn behavior in terms of the following criteria: Group I—mild, Group II—moderate, Group III—severe.

The selection of the patients was made by going through various wards, speaking with ward personnel, interviewing patients and choosing those who would best fit the desired categories. Their records were then checked to assure that the diagnoses and length of hospital stays fitted the needs of the experimental design. In this way we felt our selection of patients was more accurate.

The design included 5 phases: Phase I—baseline studies; Phase II—comparison of placebo and active treatment groups; Phase III—active treatment of all patients; Phase IV—reinstitution of a comparison of active treatment and placebo groups; Phase V—post-treatment evaluation.

Phase I. Baseline studies were conducted after the patients had been off all medication for 1 month. These studies were continued over a period of 2 months during which the patients were still off medication, and a second baseline rating was made at the end of this time.

The studies included observations made by psychiatrists, nurses and psychiatric technicians, and laboratory determinations by laboratory technicians. The psychiatrists were responsible for the psychiatric, physical and neurological evaluations. They also completed the Wittenborn Psychiatric Rating Scale, the Wittenborn Supplement for Chronic Schizophrenic Patients and the Standard Mental Status. The nurses were responsible for physiological studies such as TPR, blood pressure, weight, appetite, sleep and bowel habits. In addition, the nurses and psychiatric technicians made the observations for the Burdock Ward Behavior Rating Scale. Two sets of these ratings were made at each evaluation period. They were made independently for each patient by a nurse and a technician.

Phase II. At the start of the treatment period, one-half of the patients, Group A, were given the active compound 2445 and one-half, Group B, received the identical-appearing placebo. This was administered by double-blind procedure so that 50% of each subgroup received the active compound. The dosage schedule for the first week was 20 mg. b.i.d.; the second week, 20 mg. t.i.d., increased to 40 mg. t.i.d. for the remaining 6 weeks of this treatment period. At the end of this 8-week period, all baseline studies were repeated.

Phase III. All patients received the active

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Asst. Med. Dir., N. J. State Hospital, Marlboro, N. J.

³ Director, Bureau of Research in Neurology and Psychiatry, State of N. J., Princeton, N. J.

compound for 16 weeks. During this phase the dosage schedule was gradually increased to a maximum dose of 80 mg. t.i.d. for a period of 2 weeks, a total of 240 mg. daily, then reduced for 2 weeks to a dosage of 60 mg. t.i.d., and for the remainder of this period a dosage of 50 mg. t.i.d. was maintained. During this period of active treatment of all patients, the total daily dosage varied from 120 mg. to 240 mg. with all patients maintained during the final 4 weeks of Phase III on a total daily dosage of 150 mg. At the end of this period all baseline studies were repeated.

Phase IV. The original active treatment and placebo groups were reinstituted on a fixed treatment schedule of 50 mg. b.i.d. for Group A. At the conclusion of this phase, all baseline studies were repeated.

At the conclusion of Phase IV Group A had been under continuous active treatment from September 9, 1959 until April 8, 1960, or approximately 7 months. Group B had been on placebo treatment for 8 weeks, on drug treatment for 16 weeks, and on placebo treatment for the final 4 weeks.

SIDE EFFECTS

The most noticeable side effect was extrapyramidal symptoms manifested mainly by rigidity of extremities, masked facies, slow deliberate gait, retardation of verbal responses and increase in salivation. These symptoms were observed in 10 of the 16 female patients in the mild and moderate groups during the period when all patients were receiving maximum medication.

One Group A male patient classified as mildly withdrawn, developed oculogyric crises during the initial medication period. This was controlled by Akineton. This same patient was off medication for 2 days prior to Phase IV and following his second dosage of 50 mg. of the drug he again developed oculogyric crises. This, I believe, can be attributed to an individual idiosyncrasy to the drug.

One Group B female patient classified as moderately withdrawn, had a reactivation of an acute catatonic stupor which required force feeding. This reaction set in after Phase III when all patients had been receiving medication. The reaction of this patient was so severe that she remained in

a kneeling, prayerful position most of the time and it was necessary to remove her from the project.

In the severely withdrawn and older age group, 3 Group B, or placebo group, female patients died as a result of severe respiratory disease during an influenza epidemic. One Group A female patient diagnosed as mildly withdrawn had a kyphoscoliosis and died during the same epidemic. Post-mortem examination on this patient revealed a very poorly developed cardiovascular system.

RESULTS

Physiological. Among the women in both Groups A and B there was a general and moderate leucopenia varying between 500 and 1000 reduction of the white blood cells. This was revealed in the testing period at the end of Phase III when all patients were on active treatment, and was apparent rather than real.

Metabolic and Biochemical. There were no significant changes in weight, blood pressure, sleep patterns, appetite or bowel habits in any of the patients on the physiological evaluations. One male patient in Group A showed a persistent 1 to 2+ sugar in the urine. However, all of his blood sugar determinations were within normal limits. Liver studies showed no essential changes.

Neurological. The only neurological findings were extrapyramidal symptoms described under Side Effects.

BEHAVIORAL

1. Burdock Ward Behavior Rating Scale. This Scale provides a measure of severity of illness and an index of response to treatment for mental patients. The Scale consists of 150 items drawn from 3 categories of observation. These categories are appearance and deportment, behavior in verbal context and adaptation to ward routine. The items were constructed so as to reflect observable units of behavior. They describe such activities as facial expression and grooming, eating and toilet habits, physical status, attitudes, cooperativeness, communicational, vocalization and speech patterns, interpersonal relations, hostility, or aggressiveness, mannerisms, affect and special symptoms.

Two baseline Ward Behavior Rating Scales were completed making a total of 5 such ratings. At each of the 5 periods 2 ratings were received for every patient, from 2 different observers. Ratings for the male patients averaged 90% reliability and for the female patients 65% reliability.

Among the males, there was a significant rise in the mean scores of Group A from the first to the final rating. Group B similarly showed a significant rise in the mean scores from the second rating period (end of placebo treatment) to the fourth rating period (end of drug treatment). Among the females the differences between these rating periods were not significant. However, over the various periods a slight trend to increase mean scores is apparent among Group A, whereas the mean scores for Group B fluctuate, showing no consistent trend.

The item analysis on this rating scale is as yet incomplete. We therefore do not know the areas in which improvement occurred.

2. Clinical Evaluations by Doctors and Nurses. Clinical evaluations were made at the end of Phase III, the period during which all patients received the drug, and at the end of the study. At the end of Phase III 2 female patients in Group A were rated much improved. At the end of the project one of these patients was rated as being worse because of increased aggressiveness on the ward. At the end of Phase III of 4 female patients in Group A rated as slightly improved only 2 retained this rating at the end of the project. One patient was rated as being worse at the end of Phase III. Four patients were rated as being worse at the end of the project. One male patient in Group A was rated as much improved both at the end of Phase III and at the end of the study. Two male patients in Group A rated as slightly improved by both doctor and nurse at the end of Phase III maintained this improvement at the end of the study. None of the males in this group was rated as being worse at the end of either Phase III or at the end of the study.

The clinical evaluation of the women in Group B at the end of Phase III shows 2 female patients much improved. At the end

of the project, after being put back on the placebo, 1 of these females was described by both the doctor and nurse as being worse. Of the 5 females in this group rated as slightly improved at the end of Phase III, there was agreement on the slight improvement of only 2 of these 5 at the end of the study.

At the end of Phase III one male patient in Group B was rated as being slightly improved by both doctors and nurses. At the end of the project 2 patients were rated as showing slight improvement. None was rated as being worse.

To sum up, 1 male patient in Group A was rated as much improved; 4 patients in Group A, 2 males and 2 females, were rated as slightly improved and 4 female patients in this group were rated as having become worse. In Group B, 4 patients, 2 male and 2 female, were rated as slightly improved and 1 female patient in this group was rated as having become worse.

PSYCHIATRIC EVALUATION

1. The Wittenborn Psychiatric Rating Scale and the Wittenborn Chronic Supplemental Scale showed no significant improvement or deterioration in either treatment or placebo group between their baseline and final evaluations.

2. The Standard Mental Status—Chronic Schizophrenia Profile consists of a checklist for items in categories such as personal appearance, observable behavior, emotional behavior or affective processes, speech and intellection or thought processes. Of the 115 items appearing in this form, 4 were found to be of statistical significance when comparisons were made of patients' profiles on the baseline and final evaluations.

An item described as "irrelevant responses to questions" showed some significant improvement in the treatment group, of whom 10 patients, 5 men and 5 women, showed improvement.

In an item rating ability to obtain and maintain attention, significant improvement was found in 5 patients in the drug group. This improvement appeared in 4 females and 1 male.

In an item evaluating inappropriate affective responses, a significant improve-

ment was found in 9 patients in the treatment group. Six of these were females and 3 were males. A partial explanation for this factor of apparent improvement may be found in the high incidence of extrapyramidal symptoms among the female patients.

In an item evaluating vagueness of verbal response a significant increase was noted in both treatment and placebo groups. Twenty-four patients, 13 in the placebo and 11 in the treatment group, showed an increase of this symptom.

DISCUSSION

This study was designed, in part, to ascertain the feasibility of using a state hospital setting and regular staff personnel on a research project in conjunction with a central Bureau of Research. The central Bureau of Research provided certain facilities and services which cannot be maintained by the average state hospital. It provided assistance in research design, periodic review of the evaluations made by the hospital staff and facilities for data processing. Biometric departments and special laboratory facilities needed in this type of research cannot be provided by most state hospitals whose main concern is the care and treatment of patients.

The hospital staff continued with its normal routine duties in addition to conducting the evaluations for this study. The staff personnel involved had been working on these wards for 6 months to one year prior to the beginning of this study. We therefore eliminated the influencing factor of introducing new personnel to our study group.

The patients were allowed to remain in their accustomed environment and were not transferred to a special research ward or

building. Those among the mildly withdrawn patients who had been previously assigned to ward duties and occupational therapy were continued in these activities. Medications were given to these patients at the same time as medicines were given other patients. We thus minimized the effects of special attention and so lessened the distinction between our research patients and the rest of the ward population.

Our research indicates that it is not necessary to maintain a special ward or building for research. It was quite possible to select patients and maintain them in their accustomed environment with no undue disruption of ward routine. The fact that behavioral disturbances showed no increase during the baseline study indicates that it is possible to eliminate all chemotherapy for a period of 3 months and still maintain patients in their usual environment. The use of regular ward personnel in research procedures was also proven feasible. However, it does require careful selection of such personnel on the basis of interest, responsibility and reliability.

With our experience of having 4 or 5 separate rating periods at which times we used 4 different rating scales, it became clear that a major need is for revision of our present tools for evaluating chronic schizophrenic patients.

SUMMARY

Our results indicate that minimal results were obtained from the use of this drug in our study of 47 patients.

The study has also indicated that the design and methodology used in this research provided an acceptable basis for collaboration between a central Bureau of Research and a state hospital staff.

CERTIFICATION IN CHILD PSYCHIATRY UNDER THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY¹

FREDERICK H. ALLEN, M.D.²

In February, 1959, the American Board of Psychiatry and Neurology made an important decision for the entire field of American psychiatry. They gave formal recognition to child psychiatry as a sub-specialty in psychiatry and implemented this decision by appointing a committee of 6 psychiatrists who were recognized as experienced in this field. This committee was responsible for setting up standards and procedures for the certification of those psychiatrists who met the minimal standards of experience and training. It was clear from the outset that this committee of 6 was to function within the framework of the parent board. It is not an independent group, but as I shall bring out, the committee has had the full and wholehearted support of the Board, and has been free to set up its standards under which it has functioned. The committee wishes to give particular credit to the leadership of Dr. Francis Gerty, who, as President of the Board, played such an important part in bringing this to fruition, and to Dr. Boyd whose work with this committee has been invaluable in guiding us in getting underway.

This decision gave a new and important professional status to child psychiatry. It was preceded by a long and, at times, turbulent process. A belief was held by many psychiatrists that child psychiatry was not a sub-specialty and that any well trained psychiatrist was, by this fact, to be regarded as competent in all phases of practice. The need for special training, therefore, was not widely accepted. Many psychiatrists feared that the recognition of a sub-specialty would weaken and fragment the profession. The opposite will result from the decision of the American Board if this decision has the full support of qualified child psychiatrists and is responsibly administered.

A brief statement of some elements in the

history of child psychiatry may help to a better understanding of some of the honest doubts and questions that had to be settled before the Board could take this action.

Influences from many sources, medical and non-medical, gave impetus to the need to gain and apply in clinical settings a deeper understanding of the childhood period and the emotional problems that arose. Some of these forces emerged out of the more dynamic psychiatry which recognized that adult disturbances were rooted in the early period of life. The childhood period was presented through the disturbed perspective of the adult patient. Important as this was, there was a growing awareness that the child, living and growing in a family, needed to be understood out of himself and that clinical facilities had to be set up to help him and his parents.

Other forces were in action: changes in child welfare practices, developments in new educational procedures and more enlightened procedures in our Juvenile Courts. All served to heighten the need for developing new procedures and a different type of clinical setup. The work of Healy in Chicago, stressing the need to understand the individual, opened up another need, *i.e.*, for a real collaboration between professional groups, the psychologist, the social worker, the psychiatrist, the pediatrician. Each of these professions needed to find an effective way of working together, all pooling their separate skills to gain a deeper understanding of the child, not as an isolated person, but as a living, adapting, growing organism. This type of real collaboration was new in those days and around this fact developed many of the resistances to child psychiatry as a sub-specialty. Clinics were under suspect of being social agencies and not medical facilities.

The Commonwealth Fund of New York entered this new and exciting field in the early twenties working through the National Committee of Mental Hygiene. They sponsored the development of special clinics to diagnose and heal the emotionally disturbed

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² 3915 Henry Ave., Philadelphia 29, Pa.

child and her family. While the early emphasis was on delinquency and its prevention, the clinics soon developed a broader purpose.

These clinics, designated as "Child Guidance Clinics," provided the first opportunity for the professional collaboration of the different disciplines. But it is significant that while these clinics emerged out of community concerns and less out of hospitals or medical schools or existing psychiatric services, they did turn to the medically trained psychiatrists for leadership. In those early days, there were no trained child psychiatrists; they had to grow with this infant field.

However, these clinics have provided over the years the first organized training program. They have joined hands in a National Association to develop clinic standards and have gradually determined what is needed for the training of professional personnel, especially the psychiatrists.

Gradually the field of child psychiatry began to emerge and as more psychiatrists were trained in special skills, the move that culminated in the decision of February, 1959, began to have more impetus. Within the American Psychiatric Association new developments furthered the recognition of this field. One of the earlier committees in this organization included in one group, the problem of the mental defective and the growing field of child psychiatry. Both fields with their interrelated interests needed special attention and the Committee of child psychiatry was formed.

The Group for the Advancement of Psychiatry, when first formed, had a committee on prevention and included all the interests of child psychiatry. The resistances encountered in setting up a special committee on child psychiatry served to indicate the extent of a belief that there was no special field. This committee was formed over the protests of many.

The thoughtful reports coming from G.A.P. and from the deliberations of the APA Committee on Child Psychiatry have played an important part in giving professional status to this field. When the Council of the APA finally approved its Committee's report that this was a specialized field needing special training for psychia-

trists, a real barrier was removed which cleared the way for the decision of the American Board.

Child psychiatry has been influenced by developments in the psychoanalytic field with the emphasis on child analysis. In turn, the developments in child psychiatry have influenced this related field. Together they have moved ahead to a deeper understanding of the child both as a biological and a social being, growing up in a family.

As our clinics for the emotionally disturbed children refined their techniques, they have come into closer affiliations with other medical facilities, particularly pediatrics. The relation between these two medical specialties would require a separate paper. It was not an easy relation but the maturing of both, each operating out of its own professional opportunities, has brought them into closer relation to each other.

This is a brief statement of how child psychiatry has emerged and how it now has the professional status of a psychiatric subspecialty. The committee appointed to implement this decision is having a hard but a rewarding task. This will be a report of a year's activity:

The first requirement for certification is that the applicant be a diplomate of the American Board. This is essential as we are not setting up Child Psychiatry as a separate profession. All those certified to date, with a few outstanding exceptions, have met this basic requirement.

The committee has been operating on the following requirements for 2 classes of applicants. Those whose major interests and activities, prior to 1950, have been with children and adolescents, may apply for certification on record and without examination. The committee has made every effort to be fair and liberal in evaluating their experience and training before 1950 and to date has certified 110 on this basis. Since the committee is concerned with those candidates currently in this field of practice, we have required that those who were previously in this field and who left it for other professional work, should indicate in this application that they have returned to this field for at least 2 years preceding application. The committee reserves the right to withhold certification on record for those

whose qualifications are in doubt, and recommend them for certification after successfully passing the examination. This group has presented many difficulties to the committee which has made every effort to be fair.

The second group of candidates are those who have completed *acceptable training* since July 1950. This is an approximate date. For example, those who completed their training in September would be accepted for examination. The committee has accepted a 6-year sequence: 2 years' training in basic psychiatry, 2 in child psychiatry, and 2 for experience. Those psychiatrists in the 3-year training programs required by the American Board of Psychiatry and Neurology may spend one of those years in child psychiatry in a training program approved by both Board and committee. Each candidate is individually evaluated on the basis of the competency of his training. Then with the additional year of approved residency training in child psychiatry and with the required 2 years of experience, the applicant will be eligible for examination.

The committee had the difficult but important problem of determining how credit could be given for pediatric training. The committee recognized the importance of pediatric training for a child psychiatrist, without making this training mandatory, which some pediatricians wanted. The committee has stated that it is desirable that psychiatrists have, as a part of their training, experience in pediatrics. In October 1959, 2 members of the child psychiatry committee, the President and the Executive Director of the American Board of Psychiatry and Neurology, met with 3 representatives of the American Board of Pediatrics. A full day was given to the discussion of this problem, focusing on the question of whether pediatric training could be substituted for the 2 years of training in basic psychiatry. The child psychiatry committee held to the importance of basic psychiatric training and agreement was reached finally on the following basis: those candidates who have had 2 years of appropriate pediatric training can offer such training as experience. This means that an applicant with this training will take 2 years of basic psychiatry and 2 years of child psychiatry and be eligible for

examination. This represents an important concession of the American Board of Psychiatry and Neurology who have agreed to admit these candidates to the basic examination in order to become a diplomate.

The committee also agreed to have a representative from the American Board of Pediatrics serve as a full member on the child psychiatry committee, as a non-voting member. Dr. Hughes has served in this capacity.

In carrying out its responsibility the committee considered the type of examination that should be set up. The decision was to start with a written examination to be followed by an oral. Two written examinations have been held in different parts of the country; 105 were approved for this examination, 73 have taken it. We found that the written examination needed to be followed by an oral and have allowed all who took this first part to take the second. The oral examination was held in Chicago, April 25 and 26, with the following results: All 73 child psychiatrists who had taken the written examinations took the oral examination and 58 were passed as qualified.

After the oral examination was completed, the committee discussed the problem of giving both a written and oral examination. The value of the dual system could now be objectively studied after a full discussion. The committee concluded that the oral examination covering the following 6 areas was most comprehensive: 1. Normal growth and development; 2. Clinical problems of the pre-school child; 3. Clinical problems of the school-age child; 4. Clinical problems in the adolescent period; 5. Inter-professional and community relations; and 6. History of, and literature in, child psychiatry.

Comparing the results of the 2 examinations, the committee has decided to drop the written examination and give in future only the oral.

Another important assignment to the committee is the evaluation of every training facility in the United States offering training in child psychiatry. To do this, the committee has drawn up an application form which has been sent out to all known facilities stating the purpose of the questionnaire and inviting them to make application to the committee if they felt they were qualified

and wanted to be considered as an approved training facility. The committee hopes to get a full quota of requests. If this happens, we will have the most complete list of training facilities, so much needed if the training listed by applicants is to be appraised for the training they have had.

As the facilities are approved by the committee, more will be accomplished. Training facilities in child psychiatry will become a recognized part of the extensive medical network in the various specialities under the Medical Specialities Board. We anticipate having the assistance of the Council of Medical Education and of hospitals in this endeavor. To further this, the committee has

prepared a brochure which will be accepted by the medical speciality board as the basis of an inspection. We have been in a sound position to make clear what constitutes a good training program.

The fervent hope of the committee is that all qualified child psychiatrists in this country will avail themselves of the opportunity to join the family of certified child psychiatrists. By doing so, they lend important support to this move to give professional status to this growing field. Each one applying makes this move more effective and insures the future of our important field of professional practice.

A STUDY OF THE RELIABILITY OF THE MENTAL STATUS EXAMINATION^{1, 2}

N. ROSENZWEIG, M.D.,³ S. G. VANDENBERG, Ph.D.,⁴ K. MOORE, M.D.,⁵
AND A. DUKAY, M.D.⁶

The primary problem in psychiatric research often revolves around the reliability of the psychiatric evaluation of the patients. Unless different psychiatrists will agree as to the clinical characteristics of these patients, any other studies done with the intention of relating them to these characteristics become incapable of comparison. For instance, it is useless to study the blood sugar levels in schizophrenics if a significant degree of agreement cannot be reached as to who is schizophrenic and who is not. The present study was conducted as part of a large research investigation of schizophrenia carried out under the joint auspices of the University of Michigan and the Ypsilanti State Hospital; and was aimed towards an inquiry into the factors influencing the reliability of the psychiatric examination.

RECORDING OF DATA

The frame of reference most commonly used by psychiatrists in evaluating their patients, particularly in a state hospital setting as in the present case, is the mental status examination. Outlines for such examinations are to be found in practically every textbook of clinical psychiatry, as well as in several volumes dealing expressly with this subject. It was therefore considered wise to begin our inquiry within this standard

framework. Consequently, a form was prepared which incorporated the majority of items included in the mental status. This form underwent several revisions as the result of clinical trials with its use, and as it was finally developed and used in this study, it included, in addition to the usual mental status items, various items pertaining to certain psychodynamic questions regarding the patient's personality, defense mechanisms, etc.⁷

In constructing the form, attention was given to the problem of recording data in a way which would enable it to be coded and processed by the IBM 650 digital computer. Needless to say, without the services of the computer the vast number of correlations involved in a study of this sort could not have been attempted.

It was necessary, then, to reduce the mental status items to a series of questions calling for concrete statements, in contrast with the usual clinical method of describing the mental status characteristics in narrative fashion. Two major approaches to this problem presented themselves, and it was decided to incorporate both approaches in the current form in order to permit an examination of the relative effectiveness of each in the clinical setting.

The first approach involves framing the questions in terms of degree of magnitude of a trait or characteristic, and calls for a judgement of the relative intensity of presence of such characteristics along a linear numerical scale (Figure 1).

There are many items of the conventional mental status which cannot readily be treated in this fashion, either because they are absolute (such as male *vs.* female) or mutually exclusive comparisons (again male *vs.* female), or represent a choice between

⁷ As finally adopted, the form included 30 scale items and 29 categorical items which were also used in a form to score Rorschach data on these patients. Comparison of Rorschach and Psychiatric scorings will be reported elsewhere (Vandenberg & Rosenzweig, 1960).

FIGURE 1

Examples of Scale Items				
1. Liability of Affect

This is the usual "rating scale" approach, and the items treated in this fashion in the present study will be referred to as "scale items."

statements not linearly related (such as facial expression and participation in interview) (Figure 2). Some items could have been presented in terms of a linear scale, but it was felt that the frequency of their occurrence was limited or questions of intensity were not sufficiently relevant to warrant the expansion of the form and total number of questions necessary to include them as "scale items."

Thus, a series of questions was prepared calling for categorical judgements regarding the presence or absence of certain characteristics (yes-no judgements) or selection of the single most appropriate statements from among several alternatives offered (multiple choice judgements). Items presented in either of these two forms will be referred to in this paper as "categorical items."

In addition, the form called for an expression by the psychiatrist of his confidence in the accuracy of his own judgement regarding each item. This rating proved

impractical in actual use, however, creating undue difficulties in the recording of data, and was therefore dropped from the study.

Altogether, there were 37 numerical scale items and 52 categorical items (36 yes-no, and 16 multiple choice), calling for a total of 89 individual judgements.

METHOD AND RESEARCH DESIGN

Three psychiatrists participated in the study. Each is Board certified, and each has intensive experience with the types of patients studied. Two of the psychiatrists are on the staff of the State Hospital, though neither had direct responsibility for the care of any of the patients in the study. The third psychiatrist is on the staff of the University of Michigan, and had no prior contact with any of the patients.

Prior to the present study, the psychiatrists used the original form and its subsequent revisions (including the final form) in trial runs with a number of randomly selected patients, until each felt familiar and comfortable with its use. No attempt at constructing a scoring manual was made, but questions of clarity or semantic problems arising out of the use of the form were discussed between the psychiatrists before beginning the study proper.

The study was conducted as follows: A number of male patients between the ages of 20 and 50 were selected at random from the hospital rolls. From this pool, patients were selected who, on the basis of review of their hospital records and questionnaires completed by their ward physicians, met the following criteria:

FIGURE 2

_____ g. Not determined	
Examples of Categorical Items (Yes-no judgements)	
2. a. Disoriented for time	yes _____ no _____ ???
b. Bizarreness of thinking	present _____ absent _____ can't say

1. Over two years in the hospital.
2. Would be expected to remain in the hospital at least 60 days more.
3. Were free from severe somatic illness that would disqualify them for biochemical study.

4. Were sufficiently cooperative to take psychological tests, collect their urine, etc.

This selection procedure, conducted by persons not participating in the Mental Status Study and without consultation with the psychiatrists, was continued until a total of 50 patients was available.

Each of these patients was then seen by the group of 3 psychiatrists sitting together. During these sessions, one psychiatrist served as interviewer and conducted the examination. The other two were non-participant observers. The role of interviewer was rotated so that each psychiatrist served in this capacity for approximately one-third of the patients. Before the patient was brought to the examining room, a summary of his history was read aloud by the interviewer from the patient's hospital chart. Immediately after the patient left, each psychiatrist completed the rating form independently and without consultation with his colleagues. The average length of the interviews was 30 to 40 minutes. The average time taken to complete the form was 5 minutes.

After a period of 6 weeks, 30 of the patients were re-interviewed using the same procedure. This time the patients were selected so that 10 had previously been interviewed by psychiatrist A, 10 by B, and 10 by C.

The role of interviewer was now rotated so that each psychiatrist interviewed 10 patients, half of whom had previously been in-

terviewed by one of his colleagues, and half by the other. The selections and rotations were accomplished beforehand by persons unconnected with the examinations, who knew nothing of the patients or the previous scorings, nor even which psychiatrist was A, B, or C.

After all the ratings were completed, the data were coded upon IBM punch cards, and two types of computations were made. Agreements between all the ratings made on each item (inter-rater agreements), and agreement of each psychiatrist with himself on each item over the two interviews (consistency scores) were calculated. The significance of the obtained agreements and consistency scores on the categorical items were calculated by comparing against chance expectation using the Chi squared method. For the scale items, the Pearson product moment correlation coefficient (r) was used to compute significance.

RESULTS AND COMMENT

A. Comparison of scale items vs. categorical items: For purposes of this study a p value of 0.1 was considered significant. Breakdowns were calculated for p values of 0.05, 0.02, 0.01 and 0.001 (see Figure 3). A comparison of the number of significant agreement and consistency scores on scale items vs. categorical items reveals a better than 0.10 chance agreement on 17 of the 37 numerical scales, while for the categorical items only 14 out of 52 scores reached this level. Thus, almost half of the agreements on the numerical scales were within the significant range, while only slightly more than a fourth of the categorical items showed this level of significance. The consistency scores show a similar pattern.

FIGURE 3
Significance of Categorical and Scale Items

P	SCALE ITEMS		CATEGORICAL ITEMS	
	AGREEMENT	CONSISTENCY	AGREEMENT	CONSISTENCY
.001	5	2	1	1
.01	10	5	2	1
.02	0	2	5	1
.05	0	5	3	3
0.10	2	1	3	4
All Levels	17	15	14	10
Total Items	37	37	52	52

As can be seen from Figure 3, the distribution according to levels of significance also strongly favors the numerical scale items. These findings indicate that reliability is significantly affected by the kind of rating technique used, and suggest that numerical scales are to be preferred over categorical judgements.

B. *Difference between raters*: An examination was made of the scoring of each item by each psychiatrist over the 50 patients. No individual scoring biases were noted. Further, the correlations on 30 numerical scales,⁸ were averaged after Z transformation (see Figure 4). This method also indicated that there were no systematic differences between the raters. These findings suggest that disagreements in rating tend to arise sporadically in individual situations, and do not tend to follow a pattern indicative of an individual rater's prejudice, background, or orientation.

In determining the reliability of the men-

^a These were scale items that appeared on both the psychiatric and Rorschach rating forms.

tal status examination it is necessary to know not only whether the psychiatrists' ratings will agree with each other, but whether the same psychiatrist will rate the same phenomenon the same way each time.

It was primarily to attempt an answer to this question that the consistency scores were obtained. Since these were chronic hospital patients, it was expected that their clinical picture would remain fairly constant over the 6 week interval of the study. At first glance, noting that the consistency scores are lower than the inter-rater agreements, one might conclude that this assumption was false.

A closer consideration of the results, however, gives pause to this line of reasoning. For we notice that on those mental status items which are least stable (lability of affect, predominant mood, facial expression, participation during the interview, etc.) we get a significantly high consistency. That is to say, those characteristics most likely to vary seem to vary the least. This would suggest that the population is in fact, unusually stable in its clinical characteristics, as had been expected.

This still leaves the question of the poorer showing in consistency as compared with inter-rater agreement scores (see Figure 5).

A comparison of inter-rater agreement scores (IRA) with consistency scores (C) reveals 4 possible categories:

1. High IRA
High C
2. High IRA
Low C
3. Low IRA
High C
4. Low IRA
Low C

FIGURE 5
High Agreement — High Consistency Items

CATEGORICAL ITEMS		SCALE ITEMS	
ITEM	IRA P	ITEM	C P
Diagnosis	.001	Organization of thinking	.001
Participation in interview	.01	Level of intelligence	.001
Facial expression	.02	Reality testing	.01

		Ego Strength	.01
		Gait	.01
		Rate of Speech	.05
		Concreteness of thinking	.05
		Appropriateness of affect	.01

When the values are high for both, the reliability is good all round, and need not concern us for the moment. When the values are low all round, we must assume that in a stable population, there are items about which (for one reason or another) there is too much uncertainty within each psychiatrist to permit reliable scoring. Where consistency is high but IRA is low, we would expect that we were dealing with terms about which each psychiatrist feels clear, but about which there are differences between the psychiatrists because of individual bias or other factors. Since it has already been indicated that individual rating bias is minimal, we would expect that the number of instances of high

C and low IRA would be small, and in fact this is the case for only 5 items (see Figure 8).

We may next consider those items on which there was high IRA but low C. (Figure 7)—This situation would imply that the psychiatrists were able to agree among themselves as to what they observed, but apparently observed different characteristics at each of the two interviews. Still assuming a stable population, one could account for these differences if one considered the psychopathology of the patient to have aspects which are not on the surface, but must be elicited by the psychiatrist during the examination. Thus, if a patient were delusional, assuming the psy-

chopathology remained present throughout the period of the study, it would remain for the psychiatrist to draw the patient into talking about or otherwise demonstrating the delusions. If the interviewer is successful, then the pathology is manifest during the interview and all psychiatrists can agree as to its presence; if the interviewer does not elicit the pathology, all psychiatrists can agree that this finding was not demonstrated during that particular interview. An inspection of the 9 items falling into this category reveals that they are for the most part traits which would not be ordinarily expected to change markedly over a short time, but are all of a type requiring elicitation by the psychiatrist. It is suggested therefore, that while there were no consistent individual differences among the psychiatrists as raters, there were differences in approach to the examination, which determined whether or not certain aspects of psychopathology were elicited during a given interview. In other words, while reliability was not significantly influenced by individual bias in interpretation of concepts or by individual capacity to make observations it was significantly influenced by individual differences in interviewing technique.

Turning attention now to those items which demonstrated poor IRA and poor consistency (Figure 6), the interpretation of results becomes more difficult and calls for an analysis of the particular items involved.

Space does not permit detailed review of such an individual analysis here, but the following factors have been suggested as a result of our examination of these results.

a. Some of the items are of such infrequent occurrence that the chance expectation is abnormally high (since chance expectation is based on frequency distribution). Thus, even 99% observed agreement is in several cases not better than chance, and hence not significant.

b. Some items are dependent upon categorical yes-no judgements, where slight differences between raters as to where to draw the cut-off line result in great differences in scoring. Such items would fare much better if presented as numerical scales.^a

c. Some items call for completely subjective emotional responses of the raters

(predominant mood, depth of affect, direction of aggression, object relationship, impulse control, etc.). That is, in order to evaluate the patient's trait, the psychiatrist must examine his own emotional response to this trait. Personality differences between the psychiatrists, day to day changes in emotional responsiveness, personal problems, etc., all would tend to affect reliability of such ratings adversely.^a

d. Certain items are poorly constructed or ambiguous (posture, predominant attitude in interview, general direction of orientation, suggestibility, level of regression) or call for information about the patient not readily available from the interview situation (extent and type of interpersonal contact on the ward, degree of fantasy life, etc.). In such cases discriminations could not be made reliably under any circumstances.

e. A number of the poor agreements suggest that some concepts in common clinical usage, which are usually taken for granted as being universally understood, are in fact unclear. This may be true for items on the form dealing with memory impairment, systematization of delusions, autistic vs. realistic concepts, symbolic thinking and autistic fantasy. There appeared to be considerable uncertainty as to what constitutes neurotic symptoms in a group that was for the most part psychotic, as well as to how much concern indicates a patient is preoccupied with a given thought. It may well be that some of the basic concepts in psychiatry require close scrutiny if communications between psychiatrists are to be at all meaningful.

For us, the most interesting finding was the high number of instances giving high IRA and high C values. It may be noted that this group also contains several items which may be considered as vague concepts (i.e., ego strength, insight, reality testing), and the question arises as to why

^a This point is well illustrated by the following: In the present study, "anxiety" was an item classified as a neurotic symptom, to be scored by "yes-no" judgement. IRA and C were both below chance. In a subsequent study, anxiety was scored alone along an 8 point scale. Six raters, rating 21 patients, showed agreements in their ratings at a .001 level of significance.

these poorly defined items fared so well while others were so poor in their reliability. We can only speculate. Perhaps there is less clarity regarding the clinical expressions indicative of autism, say, than regarding the clinical manifestations of impaired reality testing. Perhaps the psychoanalytically derived concepts have become more familiar and are better understood than the traditional, more descriptive ones.

Finally, we may consider diagnosis. This reached a .001 *p* value even though a categorical item.¹⁰ There were a number of disagreements with the diagnosis carried on the patient's chart, but the panel of psychiatrists in this study agreed between themselves 96% of the time. This in itself is rather remarkable, and suggests some sort of common diagnostic framework at least shared by these 3 psychiatrists. The fact that diagnostic agreements far exceed agreements on subitems may indicate that the diagnostic formulation was made independent of at least most of the specific criteria appearing in the form.

SUMMARY

A mental status rating was developed incorporating two major scoring techniques: the linear scale; and categorical judgements on yes-no or multiple choices.

Using this form, 50 chronic hospitalized patients (over 2 years in the State Hospital) were evaluated independently but simultaneously by 3 Board-certified psychiatrists, one of whom served as interviewer, and the other two as non-participant observers. The role of interviewer was rotated, each psychiatrist interviewing approximately one-third of the patients. After a 6-week interval, 30 of the patients were re-evaluated by the same psychiatrists, each patient having a different interviewer than before.

The obtained agreements on ratings of each item, as well as comparison or ratings of each psychiatrist with himself on first and second interviews (consistency scores), were calculated. The significance of the agreement and consistency scores was eval-

uated using the Pearson product moment correlation coefficient (*r*.) for scale items, and by comparing against chance expectations by Chi squared (X^2) for categorical items. Several thousand calculations were performed using the IBM 850. The data breakdown was designed to demonstrate the effects upon reliability of differences between interviewers, differences between raters, changes in patients over time, and the limitations of the rating methods.

CONCLUSIONS

1. Scale items fared consistently better than categorical items, with better than .10 chance agreement on 17 of the 37 numerical scales but on only 14 of the 52 categorical items. The consistency scores were similar. These findings indicate that reliability is greatly affected by the kind of rating technique used, and suggest that numerical scales are to be preferred.

2. There were no systematic differences between the raters.

3. Items normally expected to be unstable (e.g., facial expression, participation in interview, affective lability), showed very high consistency over the two interviews, suggesting that these patients did not change very much during the 6 weeks interval, as was to be expected since the population consisted of chronic hospitalized patients.

4. Certain normally stable items (e.g., projection, delusions, defective orientation), while showing good agreement between raters at each examination showed poor consistency between examinations, suggesting that different interviewers may tend to bring out different manifestations of psychopathology in the patient, which then are recognized by all raters with good agreement.

5. Breakdown of scores on specific items revealed some unexpected discrepancies which are difficult to interpret, but may suggest a need to re-examine the operational definitions of some psychiatric concepts usually taken for granted.

6. Agreement on diagnosis exceeded a significance level of .001.

¹⁰ The question called for a yes-no judgement regarding schizophrenia vs. not schizophrenia.

A DAY CARE CENTER IN A STATE HOSPITAL¹

LEON A. STEIMAN, M.D., AND ROBERT C. HUNT, M.D.²

Day care of the mentally ill within the community, in a hospital setting but without isolation from home, family and community, has grown in popularity over the past 10 or 12 years.

It was around 1938 that Dr. Helen Boyle began admitting psychiatric patients to a general hospital in Hove, England. About 1945 Dr. Joshua Bierer started experimenting in the same direction, in his attempt to extend the principles of "social psychiatry" to the everyday treatment of patients.

The first day hospital was set up in 1946, by Dr. Ewen Cameron, at the Allan Memorial Institute, Montreal, Canada. Five years later, a similar day hospital was created by Dr. Moll, as part of a psychiatric ward at the then new Montreal General Hospital. Both proved to be outstanding successes and, in 1954, the first night center was established at the Montreal General Hospital. In 1951, an extensive plan for day care in connection with large mental hospitals was set up in St. John's, Newfoundland.

The day hospital plan in New York State was first proposed in the "Nine Point Program" published in October, 1955, by the Commissioner of the Department of Mental Hygiene, Dr. Paul Hoch. This program called for the establishment of 2 day hospitals, one in Brooklyn and the other in Poughkeepsie. The purpose of the Brooklyn setting was to serve selected patients attending the Brooklyn after-care clinics, all of whom are on convalescent care from state hospitals. The Poughkeepsie unit, however, was to concentrate more on community-type referrals drawn from a "random segment of population." These day hospitals were set up as independent state pilot projects, with their own budgets and organizations. This was, so far as we are aware, the first deliberately organized and planned ef-

fort by a state hospital in this country to provide day care on a non-selective, comprehensive basis.

The Poughkeepsie psychiatric day hospital opened July 2, 1956, in the Hudson River State Hospital, under the neutral name of "Day Care Center." Despite its location on the grounds, the administration thought it important at that time to dissociate the service in the public mind from the state hospital, and the center was given its own separate quarters, entrance, staff, and special stationery. Although basically independent, the center depends upon state hospital diagnostic facilities such as X-rays and laboratory services.

The center is located in a self-contained wing, partitioned into space units for offices and various types of therapy. The treatment area includes the somatic unit, with 10 beds for sub-coma insulin therapy and recuperation from electroshock treatment, plus facilities for recreational and occupational therapies. The library, with a stage setting for psychodrama, serves also for group psychotherapy and staff conferences.

The staff of the Day Care Center consists of: 2 psychiatrists, 2 psychiatric registered nurses, 10 psychiatric aides, 1 psychiatric social worker, 2 occupational therapy instructors, 1 recreational instructor, 1 half-time clinical psychologist, and 1 stenographer-receptionist.

Most of the staff members were recruited from the local state hospital, and although the majority had years of experience with mentally ill patients, initially they were given a 6-week training course, to prepare for the specific requirements of this new facility. In-service training has been continued with bi-monthly team sessions, at which the patients' behavior, problems, achievements, etc., are discussed and new admissions presented.

The center is open from 8:00 A.M. to 4:30 P.M., Monday through Friday. Anyone over 18 within commuting distance can apply for treatment. There is no commitment; no compulsion of any kind. Patients

¹Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

²Hudson River State Hospital, Poughkeepsie, N. Y.

are referred by physicians, clinics, agencies, and occasionally by the Court. Self-referrals are accepted, if suitable, as are patients discharged from the state hospital who are still rather ill and in need of intensive treatment.

No particular distinction is made as to the type of illness, as the operational structure and staffing permit treating the seriously ill. Experience has shown that the contraindications for day care need be few, although grossly disturbed, highly aggressive or greatly destructive patients should not be admitted. The screening process selects patients who can be helped in a day setting, whose admission to a state hospital may thus be prevented. The screening process is also used to refer patients for help to other agencies, mental health clinics, counsellors, etc.

In practice, the majority of patients screened out are those considered suitable for fully ambulatory treatment and not ill enough to warrant admission for day hospital care. It is a rare patient who is considered too ill for day care, provided the family is able to offer supervision the rest of the time. The liberal intake policy has been justified by a complete absence of suicidal attempts or seriously aggressive acts. Seriously ill patients with potential for such behavior are given emergency attention and placed under treatment the day of referral.

The Poughkeepsie day hospital offers a comprehensive treatment program tailored to the needs of the individual patient and his particular problem. Treatments available include ECT, sub-coma insulin treatment, and all forms of psychotherapy, ranging

from intensive techniques to directive and supportive. Group therapy is widely practiced. Pharmacological and physical methods are used, when necessary, as adjunctive to individual needs. The program also includes social casework, and therapeutically oriented occupational and recreational activities. There are no fixed rules about the therapies—timing, duration or overall length. There are, moreover, no fixed rules about patients' stay at the center. The majority of newly-admitted patients attend 8 hours a day, 5 days a week. As improvement takes place this is commonly reduced to 3 days a week or less, finally tapering off to supportive sessions once or twice a month.

The treatment program is not limited to the patient; it also involves his family. A quite successful therapy program with relatives is carried out at the center on weekdays and Sundays by the psychiatric social worker. Planned, structured sessions held with individual families and with groups contribute greatly to better understanding of the patient's emotional problems by his family.

In the first 3½ years, there have been admitted to the day care center 508 patients from 650 applications processed. Of the 142 deferred cases, some lacked motivation for treatment; others did not fit into the program. Many were referred to agencies, counsellors, clergymen and mental health clinics. A few were grossly disturbed, highly aggressive and destructive patients who would have disrupted the normal course of family, community or facility life.

Schizophrenic reactions range from the

Psychoneurotic disorders	161	31.7%
Schizophrenic reactions*	138	27.1%
Involutional psychotic reactions	77	15.2%
Transient situational personality disorders	39	7.7%
Chronic brain disorders	29	5.7%
Personality disorders	29	5.7%
Affective reactions	21	4.1%
Unclassified	6	1.2%
Acute brain disorders	5	1.0%
Mental deficiency	3	.6%
Total	508	100%

pseudoneurotic to the psychotic. We believe these cases are suitable for sub-coma insulin treatment in a psychiatric day hospital, and that their chance of resocialization in a propitious atmosphere is relatively good. The members of the involuntal group show most gratifying results, from ECT in particular.

TABLE 2
Source of Referrals

	NO. OF PATIENTS	PERCENTAGE
Physicians	185	36.4%
Self-referrals	176	34.6%
Other sources	40	7.9%
Mental health clinics	39	7.7%
Area agencies	36	7.1%
State hospitals	32	6.3%
Total	508	100%

Referring physicians include psychiatrists in private practice. These totals speak for the highly gratifying relations with the community's local private psychiatrists, general practitioners and agencies.

TABLE 3
Dangerous Tendencies

	NO. OF PATIENTS	PERCENTAGE
Latent suicidal	84	16.5%
Overtly suicidal	48	9.4%
Highly disturbed	11	2.2%
Homicidal tendencies	8	1.6%
Total	151	29.7%

Most of these patients with dangerous tendencies are commonly thought to require detention in a state hospital. Most of these have responded to treatment, and there have been no tragedies.

TABLE 4
Age Distribution

GROUPINGS	NO. OF PATIENTS	PERCENTAGE
18-29 years	125	24.6%
30-39 years	158	31.1%
40-49 years	94	18.5%
50-59 years	61	12.0%
60-69 years	11	2.2%
Total	508	100%

Sex Distribution

Male	183	36.0%
Female	325	64.0%

The relatively small geriatric group is a reflection of our admission policy of taking in only patients who are in need of treatment, not custodial care. Since the establishment of the center, the female admission rate has remained consistently twice the male rate.

TABLE 5
Length of Treatment

	NO. OF PATIENTS	PERCENTAGE
Less than 3 months	212	50.7%
3-6 months	128	30.6%
6 months-1 year	47	11.3%
1-2 years	28	6.7%
Over 2 years	3	0.7%
Total	418	100%

TABLE 6
Case Loads

YEARS	AVERAGE MONTHLY CENSUS	AVERAGE NUMBER IN FULL PROGRAM*	AVERAGE DAILY ATTENDANCE
1956-1957	50	12	10
1957-1958	72	18	14
1958-1959	84	24	26
1959-1960	94	62	35

* Average number in attendance from 1-5 full days a week.

The sustained increase in number of patients in attendance at the center is gratifying evidence of community acceptance. It is also somewhat dismaying to see case loads so rapidly approaching the maximum capacity of the center, and to be faced with the prospect of having to set up a waiting list.

TABLE 7
Condition on Discharge

	NO. OF PATIENTS	PERCENTAGE
Much improved	147	48.7%
Improved	50	16.5%
Slightly improved	51	16.9%
Unimproved	54	17.9%
Total	302	100%

By the rather rigorous criteria used, almost half the patients were restored to a good level of functioning and 82% showed some degree of improvement. Not included are an additional 116 admitted but not

treated; some of these were withdrawn, after screening, by families who felt unable to accept responsibility to care for the patients outside of hospital. Others failed to report for treatment, and some were admitted only for study and referral.

TABLE 8
Treatments Applied

	NO. OF PATIENTS	PERCENTAGE
Electro-convulsive therapy	97	19%
Sub-coma insulin therapy	68	13%
Drug therapy	217	42%
Individual psychotherapy	341	67%
Group Psychotherapy	185	36%
Occupational therapy	434	85%
Recreational therapy	483	95%

Somatic therapies, including ECT, insulin and drugs, have been used much more liberally than is usually the case in ambulatory practice. This reflects the type of case material—major psychoses and acutely ill psychoneuroses considered much too ill for office treatment.

CONCLUSIONS

The main objective of the Day Care Center was a pilot demonstration of the extent to which day care could substitute for and supplement hospitalization in the care of the mentally ill, while also establishing a closer relationship with the community. The psychiatric day hospital has proven a most successful practical application of psychiatry to the community care of these patients. It is our conviction that such a setting, serving a large number of severely ill patients, constitutes a most efficient and readily acceptable way of providing help for the mentally ill, since it maintains contact with home, family and community throughout the period of treatment, thus avoiding hospital dependency and regression, and easing readaptation to outside life.

Community acceptance of psychiatric treatment on a day-care basis has exceeded all expectations. The understanding and

good will generated are given not only to the center, but also to the parent hospital, the Department of Mental Hygiene, and psychiatry in general, and the original efforts to dissociate the day service from the state hospital are no longer necessary.

The project has demonstrated that it is possible to treat effectively and safely in a day hospital many patients so ill that they would be hospitalized, were this service not available. It has unquestionably prevented many an admission to the state hospital. It would be tempting to promise a consequent reduction in state hospital admissions, but this would be naive. The fact is that hospital admission rates in the area served by the day center have gone up sharply to the highest level in history, and higher than in any other county in the state during the period of the center's operation. It is our impression, however, that there has been a significant reduction in the number of chronically disabled mentally ill, which can be related to the effectiveness of the hospital program in general and of the day hospital in particular. Other studies now in progress should yield documentation of this impression at a later date.

SUMMARY

1. A day hospital was opened at the Hudson River State Hospital on July 2, 1956.

2. The day center treats seriously ill psychotic and psychoneurotic patients, including those with dangerous tendencies.

3. Since the opening, 508 patients have been admitted and the number under treatment is increasing steadily.

4. Physicians have referred 36.4% of the patients, and 34.6% were self-referrals.

5. There are few clinical contraindications to day hospital treatment.

6. Patients and their families readily accept psychiatric treatment when offered on a day basis.

7. Day care is a safe and effective method of treating many seriously ill, and is particularly valuable in that it maintains contact with home, family and community, and avoids hospital dependency.

THE STUDY OF MOTOR DEVELOPMENT IN INFANCY AND ITS RELATIONSHIP TO PSYCHOLOGICAL FUNCTIONING¹

BARBARA FISH, M.D.²

There has been a growing interest in the role which organic factors may play in a wide variety of psychiatric disorders in children, although these disorders are not associated with structural abnormalities of the brain. The development of techniques for studying specific disturbances in children with known organic brain disease, has made it possible to study similar mechanisms in children with milder handicaps in which the etiology is still obscure.

Immaturity and poor organization of functions under control of the central nervous system can be seen in tests of motility (3), perception (1, 4, 10, 25) and intelligence (27) and in the EEG (18). Disorders of these functions, similar to those in children with known brain damage, are found in many children with language (6) and reading disabilities (5, 23, 24), and in a large number of children whose behavior disorders are accompanied by less specific impairments, but who resemble brain-damaged children in their hyperactivity, impulsivity and low threshold for anxiety (9, 19, 26). Similar disturbances in motility, perception and intellectual functions are also found in some children with schizophrenia, but in this condition the dysfunctions are marked by the changing and erratic qualities peculiar to this illness (2).

Organic factors may be investigated in infancy as well as in childhood and later life. Gesell demonstrated many years ago that children with organic brain damage can be diagnosed in the first months of life on the basis of disturbances in motor and adaptive development (16). Using the Gesell examination, the author found that there were abnormalities of neurological maturation as early as 1 month of age in an infant who later developed clinical

schizophrenia. This infant showed a disorganized postural development, with a retardation to less than 50% of normal, followed by an acceleration of $2\frac{1}{2}$ times the normal rate, and an abnormal scatter between different aspects of development at any one examination. These features were accompanied by disturbances in alertness, physical growth, and autonomic functions (12). Milder developmental disturbances were found in 3 infants who developed behavior disorders, which were much more severe than any seen in the remaining infants who showed no developmental disturbances in infancy (11). Data from this study and retrospective studies of schizophrenic children indicate that there is no fixed neurological defect during infancy, but rather a disorder of the timing and integration of neurological maturation. It was hypothesized that poor integration of early neurological development in infants with schizophrenia is a more primitive manifestation of the same underlying disorder of integration that is manifested in adult schizophrenics by the disorganization of complex psychological functions (13).

The current study analyzes the histories of children with a variety of psychiatric disorders, to investigate whether any correlation exists between abnormal neurological development in infancy and psychological functioning in later childhood. With all the inaccuracies of a history taken 3-8 years after the fact, would it be possible to find any relationship between disturbances of early motor development and the level of later intellectual functioning, and the type and severity of psychopathology?

METHOD

The 85 children used for this study represent 90% of the children under 12 who were treated in the author's private practice in the last 7 years. A detailed history of pregnancy, birth and early development was obtained by the author as part of the

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Children's Service, Bellevue Hospital, and Associate Professor Clinical Psychiatry, New York University School of Medicine.

initial psychiatric history. The child's history, as recalled by the parents, was supplemented whenever possible by data recorded during infancy in obstetrical and pediatric records, and in baby books and dated snapshots.

The initial evaluation of each child included psychiatric and neurological examinations by the author, and complete psychological testing.³ Younger children were given the Gesell Developmental Tests and the Stanford-Binet; older children were given the Wechsler Intelligence Scale for children and the Bender-Gestalt test, in addition to projective and academic tests.

Each child was diagnosed as having schizophrenia, organic brain disease or primary behavior disorder. Of the 28 children diagnosed here as being schizophrenic, 24 were independently diagnosed as schizophrenic by other psychiatrists. One additional child was diagnosed "psychosis with mental deficiency" elsewhere. The 6 diagnoses made here of organic brain disease were also independently confirmed for 5 of the children; the 6th had been reliably diagnosed as suffering from cretinism in infancy, and had responded to thyroid medication. The remaining 51 children were diagnosed as having primary behavior disorders. Only a few of these children were ever seen by other psychiatrists.

The rating of abnormal neurological development in infancy was limited to an analysis of postural development and locomotion, since this was the only area in which adequate data were available. The extremely important development of fine coordination is almost never recalled or recorded by anyone, including pediatricians. Abnormalities of alertness and activity were recalled by some parents, but the observations were too subjective to compare in different subjects.

Postural development was first analyzed for single deviations from Gesell's norms (16). Single landmarks were rated as "accelerated," if the child acquired a skill so early that his development at that point was 140% of normal; similarly, landmarks were rated as "retarded," if the skill was

acquired so late that development was only 70% of normal (Table 1). Single deviations of this type are a fairly frequent occurrence and were considered to be minor abnormalities. Only a series of 2 or more such retardations was considered to be a "major deviation." Early postural development was also considered to show a major deviation, if it exhibited the type of longitudinal irregularity which had been found in the earlier studies of schizophrenic children (13). Thus, a major irregularity was noted, if the child's development showed both retardation and acceleration, one after the other. The underlying disturbance on which attention was focused was a disturbance of the integration of development, rather than merely slow or fast development. It was assumed that development is disorganized, if it is "out of step" with itself, and shows marked changes in rate or changes in the usual sequence of postural control, as opposed to development which merely deviates from the statistical norms. In the direct studies of development, it is also possible to measure the spread between different aspects of postural development on each examination, and the spread between postural development and fine coordination (12). The data in the current study, obtained by history, were not detailed enough for such an analysis and could only be rated for gross longitudinal irregularities (Table 1).

RESULTS

When the children in each diagnostic category are divided according to I.Q., all

³ The author is indebted to Florence Halpern, Ph.D., and Joan Havel, Ph.D. for the psychological testing.

of the severe disturbances in intellectual functioning occurred in the groups with schizophrenia and organic brain disease (Table 2). Of the 28 schizophrenic chil-

TABLE 2
Distribution of I.Q.'s in Each Diagnostic Group

	UNDER 70	70-90	OVER 90	TOTAL
Organic Brain Disease	3	2	1	6
Schizophrenia	11	9	8	28
Behavior Disorder	0	0	51	51

dren, 11 had I.Q.'s under 70, 9 had I.Q.'s between 70 and 90, and only 8 had I.Q.'s above 90. Five of the 6 children with organic brain disease had I.Q.'s under 90, 3 of them under 70. In contrast to this, all of the children with primary behavior disorders had I.Q.'s over 90. Since all 85 children came from families with average to superior intelligence and educational background, and were not exposed to environmental conditions which might depress intellectual functioning, their I.Q.'s tend to reflect the severity of their psychopathology.

Poor integration between various intellectual functions also occurred more frequently in the groups with schizophrenia and organic brain disease (Table 3). More

TABLE 3
Incidence of "Scatter" Between Verbal and Performance Scores

than 10 points difference between Performance and Verbal scores on the WISC (or Adaptive and Language scores on developmental testing) was taken as the measure of abnormal "scatter." All of the children with organic brain disease showed this degree of scatter, as did all the schizophrenic

children, except for 4 with I.Q.'s under 70. Less than half of the children with primary behavior disorders showed marked scatter.

In Table 4 the incidence of each type of motor development is indicated for each diagnostic and I.Q. category. Major irregularities in development, with both retardation and acceleration, occurred most frequently in schizophrenic children with I.Q.'s under 70. However, this type of irregularity also occurred in 2 children with milder psychological dysfunction. One was a schizophrenic boy of average intelligence; however he was the only one of the bright schizophrenic children who had been considered bizarre since he first entered school. The other was a hyperactive girl with average intelligence who had always had moderate anxiety and who developed a school phobia at 9 years of age. She was considered to have a behavior disorder of only moderate severity.

Multiple retardations occurred most frequently in the children with organic brain disorder, but also occurred in schizophrenic children with I.Q.'s under 90. The degree of early motor retardation was comparable in the 2 groups.

Single (e.g., "minor") deviations occurred in 25-33% of the children of each diagnostic category (Table 4). Two-thirds to

TABLE 4
Distribution of Deviations in Motor Development

Single Devia- tion	4	5	1	17	
No Devia- tion	1	1	3	6	33

three-fourths of the children with average intelligence had no history of deviations in motor development, regardless of whether their diagnosis was schizophrenia or primary behavior disorder.

Although grossly irregular and retarded motor development occurred most frequently in the schizophrenic children with the lowest I.Q.'s, almost half of these children regressed after a history of relatively minor motor deviations. At any time from 8 to 30 months of age they became withdrawn and spoke less, if language had been present. These regressions were usually marked by diminished activity. Parents stated "he seemed to lose life," "moved less," "slept more," or "moved more slowly." However, when this change in motor activity was not accompanied by any gross loss of established postural control, it was not reflected in the quantitative scoring.

Except for 2 children with organic brain disorder, there was no association of serious complications of pregnancy or delivery with the major deviations of motor development. The complications which were considered to be significant included bleeding or toxemia during pregnancy, prematurity, erythroblastosis fetalis and neo-natal cyanosis. Such complications occurred in 7 children with histories of normal motor development or only a single deviation; (2 schizophrenic children with I.Q.'s of 85 and 100, and 5 children with primary behavior disorders). Complications during pregnancy and delivery did not occur in any of the children with schizophrenia or behavior disorders who had major deviations in postural development; however, the mothers of 2 of them had virus infections (mumps and "flu") at the time they delivered.

DISCUSSION

In a study such as this, where data on early development were obtained by history, the presence of an abnormal history is more significant than the absence of such a history. One cannot know how many of the children with negative histories would have shown minor or major deviations, if their development had been examined carefully during infancy. A study based on historical data is obviously subject to many distortions. The positive histories were checked through other sources, but it was not possible to make any correction regarding the negative histories for the complex factors which caused some parents to notice less,

or to forget more, than other parents. The child's age when the history was obtained, seemed to make little difference; as many histories of early deviations were obtained on children who were older than 6 years as were obtained on younger children.

The number of negative histories would also tend to increase, since the analysis of deviate development had to be limited to the one variable of postural control. Such a method misses neurological deviations that show up in the scatter of postural development or in disturbances of alertness, autonomic functions, physical growth and the development of fine coordination and visual motor organization. Analysis of any single function, such as postural control, will miss disturbances of neurological integration, when the major effects are in these other areas. A complete study of early integrative capacity can therefore be made only on the growing infant; the study of his history will yield only fragmentary data.

In view of the limitations of the method, it is noteworthy that it was possible to pick up histories of significant deviations of early motor development, not only in half the children with organic brain disease, but also in a number of schizophrenic children. These motor deviations indicate that there is some involvement of the central nervous system in certain schizophrenic children before the age of 2 years, although later on they do not show any gross motor dysfunction. Neurological involvement that was severe enough to be reflected in a history of disturbed motor development occurred more frequently in the schizophrenic children with I.Q.'s under 70. Clinically these children showed the features of early infantile autism. Follow-up studies on this sub-group of schizophrenic children show that the course of the child's illness appears to be almost completely independent of the external influences of parents, schooling and psychiatric treatment, and to depend almost entirely on whether the child retains any inner capacity for further development (7). One might say that these children with the most severe form of childhood schizophrenia show the greatest preponderance of constitutional factors, on the basis of the fol-

low-up studies. The importance of constitutional factors may also be reflected in their neurological deviations in the first 2 years of life.

Pollack and Goldfarb have shown that even over 6 years of age there are more signs of neurological dysfunction in schizophrenic children with lower I.Q.'s (below 80-90). More of the children with impaired intellectual functioning showed abnormal postural and vestibular responses(22), persistent errors on the Face-Hand test (21) and confused orientation as to time and place(20). These studies of school age schizophrenic children indicate that disturbances in integration that are severe enough, to interfere with intellectual functioning, also tend to be associated with disturbances in motor and perceptual functions. The present study suggests that this disturbance of neurological integration starts before 2 years of age in many of these schizophrenic children with severe impairments in later psychological functioning.

The ability to define sub-groups of childhood schizophrenia in terms of different developmental patterns and specific impairments in function is essential for clinical management of these children. Psychiatric treatment must be based on a realistic appraisal of the child's prognosis. The child's educational program must be geared to his intellectual capacities and to his particular disturbances in perceptual, visual motor and language functions. Frequently methods used in training brain damaged children are helpful, when adapted to the special problems of the schizophrenic child(17). The degree of intellectual impairment not only limits the effectiveness of psychological measures, but it may also affect the degree of response to physiological measures(14).

However, the existence of important clinical differences between sub-groups of schizophrenic children does not necessarily mean that these differences arise from different etiological factors. The schizophrenic children with lower I.Q.'s and more evidence of neurological disturbance may merely represent a more severe variant of the illness. There was no evidence in this study that prenatal or paranatal complications

contributed to this more severe picture, but obviously much larger studies are needed to decide this point.

The fact that some schizophrenic children shift from more severe to less severe clinical pictures and vice versa(2, 8) tends to substantiate the concept of an illness with courses of varying severity(15). In this study several children who showed relatively little neurological disturbance in the first year of life, regressed shortly thereafter so that they resembled the children with severe disturbances in the first months of life. The opposite type of course also appeared in 2 children with major deviations in the first year; one developed a schizophrenic psychosis, but functioned intellectually in the average range (though well below his normal sister), the other showed a clinical picture later that was indistinguishable from the other children with primary behavior disorders. In an earlier study of developing infants, 3 infants who had milder deviations similar to those of a schizophrenic infant, showed behavior disorders in later childhood that were much more severe than those of the normally developing infants studied by the same methods(11).

The data suggest that rather than any absolute division of schizophrenic children into those with and those without central nervous system involvement, there may be a spectrum of varying degrees of developmental disturbance. Similar factors may even be involved in the lower threshold for anxiety in some children with primary behavior disorders. Environmental factors would be relatively less important, the more severe the intrinsic tendency to poor integration of development. Whereas with milder intrinsic disturbance, environmental stress or support would play an increasingly important role. The severity of later impairments would depend on such critical factors as the timing and duration of early neurological disturbances, and whether the child's environment tended to exaggerate or to counteract his particular difficulties.

SUMMARY

The analysis of early postural development and locomotion can be used as one measure of the integration of central nerv-

ous system maturation in the first 2 years of life. Using this index, involvement of the central nervous system was found in the histories of half the children with organic brain disorder and half the children who had severe schizophrenia with defective intellectual functioning. However, there was no absolute division of children with schizophrenia or primary behavior disorders into those with and without evidence of early neurological disorder. It is suggested that there may be a spectrum of developmental disturbances and that the severity of these may be related to the difficulties some individuals experience in maintaining psychological integrity in the face of stress.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

STUDY OF BUTYRYPERAZINE (BAYER 1362)

HERMAN C. B. DENBER, M.D., ELIZABETH ROSS, M.D.,
AND PAUL RAJOTTE, M.D.¹

Butyrylperazine(1) was found to be more potent and to produce fewer disabling side effects than thioperazine(2). This report deals with the use of 3-n-Butyryl-10 (3' dimethylaminopropyl) phenothiazine in 20 acute and chronic psychotic female patients from 4 to 74 days.²

The setting (a therapeutic community) has been described in detail elsewhere(3). The multiple observer technique was used.

The patients ranged in age from 18 to 56 years, with 16 between 30-49 years. Eighteen were schizophrenics and 2 suffered from a manic-depressive psychosis. Eleven patients had 1 to 4 previous hospitalizations; 7, 5-8; and 2, 10-13.

The duration of treatment was 4 days in 1 patient; 10-29 days—4 patients; 40-59 days—8 patients; 60-74 days—7 patients. The initial dose was 5 mg. q.i.d. I.M. in 14 patients. The final dose ranged from 5 mg. t.i.d. to 100 mg. t.i.d. (orally). Extrapyramidal reactions were noted in 8 patients; 5 complained of excessive drowsiness. There were few other side reactions. Hematologic or liver chemistry changes were not observed.

Four patients were much improved (one of whom relapsed subsequently); 4 were improved; 11 were unchanged; and 1 was worse.

The compound showed fewer toxic side effects than many other available drugs,

and patients did not complain of feeling like "lead." The drowsiness was not dose-related. The use of increasingly higher doses (300 mg. daily—4 patients) did not materially influence the end result. Neither dyskinesia nor other neuromuscular involvement was observed, contrary to other observations(1). Since acutely ill patients did not respond rapidly, it would seem that butyrylperazine has a slow onset of action. Patients discontinued from the drug relapsed, at times within 48 hours, suggesting a rapid excretion. Although many of the present group of patients were chronically ill, thioperazine achieved a substantially better result in a similar patient sample(4). The effectiveness of butyrylperazine appears to lie between chlorpromazine and the other piperazine phenothiazines.

We were unable, therefore, to confirm the German observations. In a review of the data with Professor Flugel and his collaborators, it was found that: 1) our highest dose (300 mg. daily) was approximately 10 times their maximum dose; 2) their incidence of extrapyramidal reactions was almost twice the present group; 3) dyskinesias occurred in 45% of their patients with none in our series; and 4) their improvement rate was in the neighborhood of 65-70%. This suggested that we were dealing with a different patient sample.

Our inability to confirm European findings with this drug, "Haloperidol" or "Taractan," has made it necessary to review the entire problem of drug evaluation as affected by genetic, socioeconomic, cultural and other factors. Little attention has been given to the setting in which drug trials are conducted. At the present time, our tentative hypothesis is that the apparently marked

¹ Research Division, Manhattan State Hospital, Ward's Island, New York 35, N. Y.

heterogeneity of the present patient population probably represents a genetically different biochemical reactivity in terms of each patient's response to treatment.

This problem is now being investigated jointly, through the use of matched samples, with Dr. D. Bente (University of Erlangen, Germany), and Dr. J. Collard (University of Liege, Belgium), and will be reported in greater detail at another time.

PRELIMINARY REPORT ON TARACTAN

JANE E. OLTMAN, M.D., AND SAMUEL FRIEDMAN, M.D.¹

Taractan² is 2-chloro-9-(3-dimethylaminopropylidene) thioxanthene. Although not a phenothiazine derivative, it is stated by the manufacturer to have tranquilizing potency similar to that of the phenothiazine compounds and also to exhibit antidepressant efficacy.

The drug was administered to 53 newly admitted patients. It was discontinued in 3 patients, leaving 50 cases for evaluation. They were all females, ranging in age from 16 to 70, with 58% in the third and fourth decades of life. Diagnostic classification is indicated in Table 1. Dosage ranged from

garded as "mixed type" and 1 as depressed. Of the 12 patients in these 2 diagnostic categories, 8, or 67%, were considered to have achieved a remission or much improved status, and 3, or 25%, were regarded as improved. It is apparent, therefore, that the drug exerts its greatest effect on patients with prominent affective components in their illness.

Of the 32 schizophrenic patients, only 2 were regarded as much improved and 3 as improved. The duration of present illness in these 5 patients was 1 year or less. In contrast, only 15% of the schizophrenics with

TABLE 1

Diagnosis	Total Number	Remission or Much Improved	Improved	Slightly or Not Improved
Schizophrenia	32	2	3	27
Schizo-affective	9	5	3	1
Manic-depressive	3	3	1	0
Involutional psychosis	4	1	1	3
Psychoneurosis	2	1	1	1
	50	12 (24%)	6 (12%)	32 (64%)

100 to 300 mg. daily, with 150 to 200 mg. as the most frequent daily dosage. The drug has been used for periods ranging up to 5 months.

Results are indicated in Table 1. It is evident that best results were obtained in the schizo-affective and manic-depressive groups. In the latter, 2 patients were re-

insignificant improvement had a present illness of less than 1 year. In 70% it was more than 2 years, and in 41% more than 5 years. As emphasized in a previous report(1), duration of present illness is a significant prognostic factor in schizophrenia. It should be indicated also that in the schizo-affective group, duration of present illness may have been a pertinent modifying factor, as in 67% of this group the present illness was less than 1 year. The sole patient in this group

¹ Newtown, Conn.

² Supplied by Hoffman-La Roche Inc., Nutley, N. J.

who failed to improve had been ill more than 5 years.

Of the 32 schizophrenics, 20 also received other ataractic drugs, either before or after Taractan or at a previous episode of illness. In 6 instances, other drugs produced a superior level of improvement, in 12 cases they were equally ineffective and in 2 the degree of improvement was similar.

Complications were absent and side-effects were few at the dosage level employed. As indicated, the drug was discontinued in 3 cases within a few days because of excessive somnolence or dizziness. In the group of 50 patients, there were 4 who complained of mild drowsiness, 1 exhibited some degree of restlessness and 1 had hypotension. Thus side-effects were definitely less than with

other drugs. One depressed patient, described briefly in a previous communication (2), who had experienced dizziness and fainting under Marplan and Tofranil, recovered uneventfully under Taractan.

CONCLUSIONS

It may be stated that Taractan appears helpful in patients who exhibit prominent affective components in their illness. It would seem to merit further study.

A PILOT STUDY OF THE EFFECTS OF PATHCOLE, A SEROTONIN ANTIMETABOLITE, ON SCHIZOPHRENIC PATIENTS

G. VASSILIOU, M.D., E. COSTA, M.D., G. BRUNE, M.D.,
CLARA MORPURGO, M.D., G. AYALA, M.D., H. E. HIMWICH, M.D.,
AND VASSO VASSILIOU, M.A.¹

PURPOSE

Accumulated experimental evidence as assessed by Woolley(1, 2) suggests that errors in the metabolism of brain serotonin may be associated with such mental states as depressions, with a deficiency of serotonin, and acute psychotic states, with an excess of serotonin. In an effort to obtain more information in this area Shaw and Woolley(3) synthesized Pathcole (6-phenylamidino-1,2,3,4, tetrahydrocarbazole). This drug, a potent antagonist to serotonin exerting tranquilizing effects in laboratory animals, was well tolerated in preliminary trials on non-psychotic human beings.

The purpose of the present study was to investigate the effects of Pathcole on acutely disturbed schizophrenic patients.

EXPERIMENTAL DESIGN

Six acutely disturbed schizophrenic patients were selected, 3 females and 3 males,

age range 19 to 38 (average 26 years). Duration of illness was less than one year for 3 and no more than 5 years for the other 3. Two had been diagnosed as chronic undifferentiated schizophrenic and 4 of the paranoid type.

Their selection for this study was based on additional independent evaluations to establish the presence of fully developed acute psychotic states. All patients presented hyperactivity, confusion, incoherent and irrelevant thought processes, delusions and one or more of the following disturbances : hallucinations, ideas of reference, flight of ideas, inappropriate affect, disorientation.

PROCEDURE

The experimental design included 3 conditions :

Condition I : A 2-week observation period following the transfer of patients in the research wards. Although an adequate knowledge of the behavioral patterns of all 6 patients was already available for comparison with possible drug changes, condition I provided for a levelling of any behavioral

¹ From the Thudichum Psychiatric Research Laboratory, Galesburg State Research Hospital, Galesburg, Illinois.

changes the transfer to the research ward might have induced.

Condition II: A 5-week period under Pathcole during which a starting dose of 25 mg. daily was increased at the end of the first week to 25 mg. b.i.d. and was raised still further in accordance with individual progress until the dose of 25 mg. q.i.d. was reached for 3 patients while the other 3 attained the dosage of 25 mg. t.i.d. Pathcole was given for 5 weeks only because of our limited supply of that drug.

Condition III: A 4-week period under placebo.

At the beginning of condition I and at the end of conditions II and III respectively, the patients had physical examinations and in addition laboratory studies including CBC, urinalysis, and liver tests. Psychological examinations included a battery of 2 projective tests (Rorschach and Draw-a-Person), and 4 subtests from the Wechsler Adult Intelligence Scale (Information, Comprehension, Similarities, Digit Symbol). During all 3 conditions patients were interviewed weekly by 6 physicians for evaluation of mental status and observations of blood pressure, pulse, perspiration, dermatographism and reflexes.

RESULTS

Two patients, A and B, showed some improvement which lasted throughout condition III. Restlessness and psychotic symptoms decreased, rapport and behavior improved. Psychological tests showed increased motor coordination for A and in addition better relations with reality and less explosive expression of emotions for B. Patients C and D exhibited a shift of psychomotor activity toward normal limits and improved ward adjustment. In patient C this improvement was maintained throughout condition III with better relations with reality, less disruptive aggression, less explosive expression of emotions, decreased number of Rorschach responses and decreased motor coordination. Patient D, after the second week of condition III, became aggressive, disturbed and was not testable. Finally patients E and F showed some improvement during the third and fourth week

of condition II. Restlessness decreased, thought processes became somewhat organized, and affect improved. In the fifth week of Pathcole (25 mg. q.i.d.) they developed, however, a temporary turbulence-like stage including motor restlessness. Their previous psychotic symptomatology was accelerated as they became combative, unmanageable and were not testable.

The observed physiological changes were definite but did not show any specific correlation with the described clinical and psychological changes. All patients presented increased pulse rate (group mean rising from 92 to 112) and reflexes became more active (group mean from 1+ to 3+). Five patients revealed moderate increases of blood pressure (group mean from 109/74 to 137/88) and in only one case did blood pressure present no significant changes. Dermatographism increased in all patients. Idi muscular reactions appeared in the fifth week of medication in all patients. Perspiration exhibited variable changes. No side reactions were observed.

There is no direct evidence that Pathcole actually entered the brain, and with techniques now available it is not possible to decide this point. Thus the results of this clinical study can not be used to substantiate nor to eliminate the hypothesis that excess of serotonin in the brain contributed to acute psychotic states. The observed moderate temporary improvements might be interrupted in accordance with Woolley's hypothesis and point to the need of more extensive studies of serotonin antimetabolites.

SUMMARY

The effects of Pathcole on 6 acutely disturbed schizophrenic patients were studied and some temporary improvements of varying durations were observed in each patient.

COMMENTS

NATIONAL ASSOCIATION FOR MENTAL HEALTH GOLDEN ANNIVERSARY¹

Fifty years ago Clifford Beers, with the encouragement and support of Adolf Meyer, William H. Welch, William James and others, established in New York City the National Committee for Mental Hygiene, which he served as secretary for many years.

Ten years ago, the National Committee merged with the National Mental Health Foundation and the Psychiatric Foundation to form the present National Association for Mental Health.

Clifford Beers had a long perspective and he foresaw growing through the years a great science-based humanitarian movement in the interests of mental health. To some of his friends, Mr. Beers' forecast seemed nothing less than visionary, but he lived to see his dream realized; and in 1930 he was the central figure in an international congress in Washington to which came delegates from more than 50 countries representing as many mental hygiene societies, to pay him tribute.

Now this great national society in its present enlarged form is 50 years old, with more than 800 affiliates and over a million members and volunteers throughout the country. The Report of the N.A.M.H. of its last year of the half-century gives a vivid picture of progress during those five decades, and of its present and continuing projects and activities.

¹ The manuscript of this comment, prepared last year, was lost sight of during the process of moving the editorial office.

Because of the importance of the events commemorated it is felt that it should be published even thus belatedly.

Ed.

This report makes good reading. It tells of the research program of the National Association under the direction of Dr. William Malamud whose views of how research should be conducted were set forth in his Presidential Address before the American Psychiatric Association in Atlantic City in May of last year. During 1959, the Research Committee of N.A.M.H. made grants amounting to \$119,418.00 to 15 research projects throughout the country. In addition, the Committee distributed \$108,700.00 granted for schizophrenia research by the Supreme Council of the 33rd Degree Scottish Rite Freemasonry Northern Masonic Jurisdiction for the year 1959. It will be recalled that during the past 26 years the Scottish Rite has provided more than \$1,500,000.00 for research in schizophrenia.

Following testimony before Congress by N.A.M.H. and other agencies the Federal Government appropriated \$68,000,000 to the National Institute of Mental Health for 1960. This compares with \$4,250,000 in 1948, since which date, appropriations for this purpose have steadily increased.

The Golden Anniversary Meeting of the N.A.M.H. last year in Philadelphia was the largest in its history with delegates from 41 states and Canada. At this meeting, tribute was paid to Dr. George S. Stevenson, retiring Director after 33 years of devoted service. He was presented with a massive testimonial volume containing letters of appreciation from government and psychiatric leaders throughout the world.

This historic Report of the National Association for Mental Health was appropriately introduced by its President, Mrs. A. Felix du Pont, Jr.

NEWS AND NOTES

DEDICATION OF THE HOUSTON STATE PSYCHIATRIC INSTITUTE.—The new building of the Houston State Psychiatric Institute for research and training in the Texas Medical Center was dedicated on February 3, 1961. The Institute is a division of the Texas Board for State Hospitals and Special Schools—C. J. Ruilmann, Director—and is closely affiliated with the Department of Psychiatry of Baylor University College of Medicine. W. T. Lhamon is Chairman of the Department and has been Director of the Institute since its formation 3 years ago.

The chief address at the dedication entitled "Service, Research and Survival" was given by Dr. Kenneth E. Appel. The dedication was made by Dr. Ruilmann and Dr. Lhamon.

At the banquet in the evening, Dr. Louis J. West gave an address entitled "The Challenge of Experimental Psychiatry." To Dr. Eugen Kahn, Professor of Psychiatry at Baylor University College of Medicine and consultant psychiatrist to the Institute, a scroll was presented in which his friends and colleagues acknowledged their indebtedness to him:

"For pioneering accomplishments in the earliest psychiatric institutes of Europe and America;

For wise counsel to the faculty of the Department of Psychiatry of Baylor University College of Medicine and the staff of the Houston State Psychiatric Institute;

For scholarly contributions as a teacher, clinician, scientist, and writer for which he is honoured throughout the world;

For the warm compassionate feelings toward his fellow men which bring to them inspiration, affection, and humor."

Both ceremonies and an open house were attended by several hundreds including members of the Texas legislature. Out of town guests included Dr. Robert L. Stubblefield; Dr. Hamilton Ford; Dr. T. H. Hill; Dr. Floyd Cornelison; Dr. Hugh C. Bledgett, Chairman of the Department of Psychology, University of Texas; Dr. Louis D. Cohen, Professor of Psychology, Duke University School of Medicine; Dr. Irwin J. Knopf, Psychologist, Southwestern

Medical School; Dr. William Hurder of the Southern Regional Education Board; Dr. Robert Sutherland, Hogg Foundation.

The new building is of advanced design and in its 70,000 square feet of space contains a 60-bed hospital, adult and child outpatient clinics and a day hospital. These will be used solely for research and training purposes.

Nearly half of the space is devoted to laboratories for biochemical, biophysical, neurophysiological, pharmacologic, psychologic and sociologic research. Staff members, who hold joint appointments in Baylor include John Kinross-Wright, Associate director, Neil Burch, William Boardman, Robert Edelberg, Seymour Fisher, Charles Gaitz, Sanford Goldston, James Knight, Irvin Kraft, and James Ragland.

AMERICAN ORTHOPSYCHIATRIC ASSOCIATION.—At the 38th annual meeting of the Association, Mar. 23-25, in New York City, Fritz Redl, Ph.D., became president for the year 1961-62.

Edward D. Greenwood, M.D., was named president-elect to take office in 1962, and Jules Henry, Ph.D., was elected vice-president.

EASTERN PSYCHIATRIC RESEARCH ASSOCIATION.—The sixth annual meeting of the Eastern Psychiatric Research Association will be held October 27 and 28, 1961 in New York City.

The theme of the meeting will be "Expanding Goals of Genetics in Psychiatry (1936-1961)."

Further information may be obtained from David J. Impastato, M.D., Secretary-Treasurer, 40 Fifth Ave., New York, N. Y.

THE INTERNATIONAL SOCIETY FOR CLINICAL AND EXPERIMENTAL HYPNOSIS.—The Society will hold its annual convention July 16-22 in Rio de Janeiro in conjunction with the Congresso Pan-Americano de Hipnologia and the Congresso Brasileiro de Hipnologia. The program will emphasize concepts and definitions of hypnosis, neurophysi-

ology of hypnosis, and medico-legal and ethical concepts in its practice. Those interested in attending or presenting papers can secure additional information by writing either : Oscar Farina, M.D., 1st Secretary, Brazilian Division ISCEH, R. Estados Unidos, F95, São Paulo, or David Akstein, M.D., President, Brazilian Society of Medical Hypnosis, Rua Cinco de Julho, 376, Copacabana, Rio de Janeiro, Brazil.

YALE UNIVERSITY SCHOOL OF MEDICINE POSTDOCTORAL FELLOWSHIPS IN PSYCHIATRY.—The Department of Psychiatry announces training fellowships focussed on laboratory work; training in clinical psychiatry is provided when required. The training is arranged to meet the specific goals and needs of each candidate.

Applications will be accepted from candidates with the M.D. or Ph.D. degree. Candidates from psychiatry should complete their second year of residency prior to their work on this program.

Stipends generally range from \$6500 to \$8500 per annum.

For further information write to Dr. Kenneth A. Chandler, Executive Director, Basic Science Program, Dept. of Psychiatry, 333 Cedar St., New Haven 11, Conn.

AMERICAN ELECTROENCEPHALOGRAPHIC SOCIETY.—The 15th annual meeting of the Society will be held at the Hotel Claridge, Atlantic City, June 9-11. The scientific program will include two symposia: 1. The Medicolegal Electroencephalogram, Dr. Isadore S. Zfass, chairman, June 10 at 2:00 p.m. 2. The Physiological Basis of Memory, Dr. Frank Morrell, chairman, June 11 at 9:00 a.m. All members of the American Psychiatric Association are invited to attend.

NATIONAL COUNCIL ON FAMILY RELATIONS.—The 1961 annual meeting of the NCFR will be held Aug. 23-25 at the University of Utah. The keynote address on "Difference, Tolerance, and Cooperation" will be delivered by Opert Tanner of the University of Utah, well known as a philosopher, great speaker, and world traveller.

Three plenary sessions will follow: "Eth-

ical Differences," "Ideological Differences," and "Religious Differences." Wallace Fulton, New York City, will act as moderator for the sessions.

EAST BAY PSYCHIATRIC ASSOCIATION.—The officers of this society for the year 1961 are as follows : President, Dr. Allen S. Mariner, San Leandro, Calif.; President-Elect, Dr. Lloyd Patterson, Berkeley, Calif.; Secretary, Dr. Melvin M. Lipsett, Berkeley, Calif.; Treasurer, Dr. Eric Plaut, Berkeley, Calif.; Elected as Councillor, Dr. John Visser, Berkeley, Calif.

A NEW UNIVERSITY POST.—President Clarence B. Hilberry of Wayne State University, Detroit, Michigan, reports the establishment of a new faculty post, the "University Professor" with its first incumbent Dr. John M. Dorsey who for the past 15 years has held the chair in psychiatry at his university.

It is understood that the duties of the new position will be quite informal. The University Professor will be able to maintain contact with students and teachers in the various departments with a view to presenting the educational process as a rounded whole rather than as merely the opportunity for the student to acquire information on a number of more or less isolated subjects in which he may find himself interested. A senior consultant, such as the new member of the faculty will be able to bring to the student both a new and broader concept of the learning experience, a wide humanistic view of what a university education can and should mean, both an outlook and an inlook on knowledge as the handmaid, though not a substitute for wisdom, leading in the direction of the ancient *nihil humani* tradition.

This new development at Wayne State University will be followed with much interest.

THE AMERICAN NEUROLOGICAL ASSOCIATION.—The 86th annual meeting of the American Neurological Association will be held at the Claridge Hotel, Atlantic City, New Jersey, June 12-14, 1961 under the

Presidency of Dr. Harold G. Wolff.

Information regarding the meeting may be obtained from the Secretary, Dr. Melvin D. Yahr, Neurological Institute, 710 West 168th Street, New York 32, New York.

INSTITUTE OF GENERAL SEMANTICS.—The 18th annual Seminar-Workshop in General Semantics—the first West-Coast Conference—will be held Aug. 12-27, 1961 at the University of California, Santa Barbara.

Enrollment limited to 60. Tuition, \$300 (includes registration fee \$30, which must accompany application). Room and meals for the period and the meetings, \$145. A few scholarships are available.

For information write to: Registrar, Institute of General Semantics, Cakeville, Connecticut.

SOCIETY FOR PSYCHOPHYSIOLOGICAL RESEARCH.—This new society will hold its first annual meeting in New York on Sept. 5 in conjunction with the American Psychological Association convention. The purpose of the society is to foster research on the somatic responses and their psychological relations in various academic disciplines including psychology, physiology, biology, psychiatry and instrumentation. All scientists interested in this research field are invited to attend the meeting and to consider membership. President of the Society is Chester Darrow, Ph.D., Institute for Juvenile Research, Chicago.

Details regarding membership and the program may be obtained from the Secretary, Albert F. Ax, Ph.D., The Lafayette Clinic, 951 East Lafayette, Detroit 7, Michigan.

THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The following were certified at New Orleans, Louisiana, Mar. 18, 20 and 21, 1961:

DEATH BY SUGGESTION.—Theodore X. Barber, Ph.D., writing in *Psychosomatic Medicine* (March–April 1961), considers reports of various forms of “voodoo death” among nonliterate people and concludes that black magic, sorcery, or suggestion have not been demonstrated to be the direct cause of such deaths; that some reported cases were apparently due to poison or organic disease, that in some instances the victim, believing death to be inevitable because of sorcery, refused food and water and died of starvation and dehydration; that the hypothesis that such death may be due to overstimulation of the sympathicoadrenal system or of the parasympathetic system is premature.

WISCONSIN PSYCHIATRIC INSTITUTE.—The Institute and the Department of Psychiatry, University of Wisconsin Medical Center, will sponsor a 3-day interdisciplinary research conference, August 29–31, 1961 on “The Physiological Correlates of Psychological Disorders.” Topics will include adrenocortical function during anxiety, psychophysiological problems, psychological factors in cardiovascular responses, and others.

Accommodations will be in lake front dormitories. Interested scientists and their families are cordially invited. Inquiries may be addressed to: Coordinator of Postgraduate Medical Education, The Wisconsin Center, 702 Langdon St., Madison 6, Wisc.

DR. BLAIN HONORED.—The Southern California Psychiatric Society at its annual meeting Apr. 29, 1961, presented a scroll to

Daniel Blain, M.D., Director of the Department of Mental Hygiene, State of California, for his long record of important contributions to the field of mental health. Dr. Blain, an international figure in psychiatry, was the first medical director of the American Psychiatric Association, and served ten years in that capacity before assuming this present post in California.

EASTERN PSYCHIATRIC RESEARCH ASSOCIATION.—The 26th meeting of this Association will be held on June 22, 1961 at 8:00 p.m. at the New York University Medical School, 30th Street and First Avenue, New York City.

Topics: 1. “The First Organization of Ex-patients of a Psychiatric Hospital—25 Years Later,” Jacob Friedman, M.D., New York City. 2. “Ambulatory Maintenance Electric Coma Therapy in Chronic Mental Illness—a 10-year Review of 50 Patients,” Emerick Friedman, M.D., Albany, N. Y. 3. “Views and Practices in Psychiatric Pharmacology,” Brian C. Campden-Main, M.D., Arlington, Va.

PSYCHIATRIC FACILITIES IN ISRAEL, 1960.—In December, 1960, I visited Israel for a short stay of 2 weeks. I shall mostly detail facilities around the intellectual center of the country, Jerusalem, but first will sketch a few observations about psychiatry in the country as a whole.

Psychiatric patients in Israel are cared for as follows: 1. The Government maintains, by far, the most facilities; 2. There are private practitioners in psychiatry and psychoanalysis, although they seem to carry less of the total patient load than in the United States; 3. Some Psychiatric treatment is provided through the various Sick Funds, of which the largest is Kupat Holim, the Sick Fund of the General Labor Federation, (the Histadrut); 4. The kibbutzim singly and jointly provide for some of their psychiatric needs, for example, they maintain a Child Guidance Center at Oranim (see; Kaffman, M.: *Am. J. Psychiat.*, 117: 732, Feb. 1961); 5. The Hadassah Medical Organization carries out extensive programs of care; 6. Other privately supported or-

ganizations offer treatment, such as the American Joint Distribution Committee which cares for aged psychiatric patients in various parts of Israel.

The rest of my observations concern Jerusalem and its vicinity, which was the main focus of my visit. Several hospitals in the Tel Aviv area are described (*in* Klein, I. J.: *Am. J. Psychiat.*, 117: 459, Nov. 1960). In the Talbieh section of Jerusalem is the headquarters of the Israel Psychoanalytic Society (Dr. Erich Gumbel, President, M. Brandt, Secretary). It is an active organization, has a training institute, and includes members in the other cities of Israel. It holds some of its meetings and conducts part of its training program in Tel Aviv. Its members devote part of their time to psychiatry—Dr. H. Winnik is Director of the Talbieh Hospital and Dr. J. Schossberger heads the "Work Village"; Dr. Gumbel is Consultant to the Child Guidance Clinic of the Hadassah Medical Organization (The Albert and Mary Lasker Child Psychiatry Department).

The Government maintains a psychiatric hospital at Eitanim, near Jerusalem. This includes a children's ward with approximately 20, mostly autistic, patients. Of its roughly 100 beds for adults half are for acutely ill patients. Eventually it is planned to expand the hospital to 250 beds. The Government also operates for chronic cases a "Work Village" with emphasis on rehabilitation and provides funds for the care of patients in other hospitals, such as the custodial hospital at Ezrat Nashim, directed by the University professor of neurology, Dr. Halperin.

The Histadrut has its own psychiatric hospital in Jerusalem, the Talbieh Hospital, which includes an outpatient clinic, and supplies money for their members' visits elsewhere, such as to the Hadassah clinics.

Dr. I. Zellermyer is the head of the department of psychiatry, Rothschild Hadassah University Hospital and Hebrew University—Hadassah Medical School. The department includes an 11-bed inpatient service for research and teaching and an active outpatient division (for description see Moses, R., and Shanani, J.: *Arch. of Gen. Psych.*, 4: 60, Jan. 1961). Members of this depart-

ment, Drs. S. R. Moses and D. Hertz, are also consultants to the Institute of Criminology of the University. In a few months this department will move from its present scattered quarters to biblically historic Ain Karem, outside of Jerusalem, where rise the fabulous modern buildings of the new Hadassah-Hebrew University Medical Centre. Careful and thoughtful planning have produced what should be one of the most efficient as well as beautiful hospitals in the world today.

Hadassah also supports the Lasker Child Guidance Clinic, directed by Dr. Joseph Oren, who with Drs. Moses and Hertz, obtained part of their training in this country.

There are other small private hospitals in Jerusalem, and there still persists the former custom of caring for psychiatric patients in private homes. The Israeli Neuropsychiatry Association, of which Dr. Hertz is Secretary, has its headquarters in Jerusalem.

Though this is not a complete description of psychiatry in Israel, by focusing on various facilities I found in Jerusalem, I am implying that Israel has a level of psychiatry which compares favorably in many ways with other modern countries.

James A. Kleeman, M.D.
New Haven, Conn.

CANADIAN MENTAL RESEARCH REWARD AVAILABLE.—The Canadian Mental Health Association's National Mental Health Research Fund is now accepting applications for its annual Research Award, approximately \$25,000.

The recipient should reside in Canada and have appropriate scientific qualifications in any of the professional disciplines directly related with mental health or mental illness. The final selection of a candidate is the sole responsibility of the director of the Fund—Dr. Ray Farquharson, M.B.E., F.R.C.P., who is also director of the Medical Research Council in Ottawa.

Letters of application should be sent not later than June 1, 1961 addressed to: Dr. Ray Farquharson, Director, Mental Health Research Fund, Canadian Mental Health Association, 11½ Spadina Road, Toronto 4.

ANNUAL INDEX

This periodical is indexed alphabetically under both Subject and Author entries.

In searching for a specific article, the Author entry should be consulted if the name of the author is known, since the complete bibliographical reference is to be found only after the author's name. When there are two or more authors for an article the complete entry appears only under the name of the first author. Under the names of each of the joint authors a cross reference is made to the original author entry.

The same applies to book reviews, the complete title of the book being listed under the author's name in the list entitled Book Reviews in the Subject Index.

Titles under the Subject Index are often inverted or shortened, and when there are two or more authors, the name of only the first is shown. For the complete author reference, the Author Index should be consulted. The Subject Index covers original articles, biographical and historical materials, book reviews, in memoriams, and editorial comments.

Complete book titles are listed under Book Reviews in the Subject Index. Ed. indicates an editorial comment; H.N. a historical note; C.N. a clinical note; C.R. case report; A.N. administrative note; and Corr. correspondence.

SUBJECT INDEX

A

- Abstract Thinking: Modes of, and Psychosis;
N. McConaghy, 106, Aug. '60.
- Academic Lecture: A Sociologist's View on
Patient Care; Leo Simmons, 385, Nov.
'60.
- Administrative Psychiatry (Review of Psychi-
atric Progress, 1960); J. Martin Myers,
649, Jan. '61.
- Administrative Therapy: Principles of; D. H.
Clark, 506, Dec. '60.
- Adolescence:
In State Hospital; James F. Suess, 891, Apr.
'61.
- Mental Hospital Treatment of Troubled
Youth; Donald M. Hamilton, 811, Mar.
'61.
- Adolf Meyer Lecture: The Study of Defect;
Sir Aubrey Lewis, 289, Oct. '60.
- Age: See Geriatrics.
- Agranulocytosis: See Psychopharmacology,
Side Effects.
- Alcoholism:
Alcoholism (Review of Psychiatric Progress,
1960); Karl M. Bowman, 628, Jan. '61.
- And the Hypothesis of Reciprocal Comple-
mentarity; A. H. Hobbs, 228, Sept. '60.
- Obsessive-Compulsive Alcoholic; Edward
Podolsky, 236, Sept. '60.
- American Psychiatric Association:
Annual Meeting, 1960 (Ed.); 82, July '60.
- Committee Structure; 943, Apr. '61.
- 116th Annual Meeting, Atlantic City, N. J.,
1960 (Ed.); 253, Sept. '60.
- Official Reports:
Coordinating Committee on the Technical

- Aspects of Psychiatry (Ed.); 265
Sept. '60.
- Editorial Board Changes (Ed.); 82, July
'60.
- Professional Standards; 757, Feb. '61.
- Amsterdam, Holland: Municipal Psychiatric
Service; Paul V. Lemkau, 779, Mar. '61.
- Anesthetic in Shock Therapy (C.N.); William
Karliner, 355, Oct. '60.
- Animal Experimentation: Behavioral Changes
During Hypothalamic or Limbic Stimula-
tion in the Monkey; Lorne D. Proctor,
511, Dec. '60.
- Aortic Graft: And Electroshock (C.R.); A. H.
Chapman, 937, Apr. '61.
- Ataraxics: See Psychopharmacology.
- Atropine-Like Poisoning Due to Tranquilizing
Agents (C.N.); Harbhajan Singh, 360,
Oct. '60.

B

- Back Ward Patients: Trifluoperazine: Report
of a Clinical Trial in (C.N.); John A.
Guido, 453, Nov. '60.
- Behavior Changes: During Hypothalamic or
Limbic Stimulation in the Monkey; Lorne
D. Proctor, 511, Dec. '60.
- Biochemistry:
Epinephrine-Mecholyl Test Applied to a
State Hospital Population (C.N.); Pan-
delis K. Pandelidis, 154, Aug. '60.
- Longitudinal Clinical and Neurochemical
Studies on Schizophrenic and Manic-De-
pressive Psychoses; Samuel Bogoch, 409,
Nov. '60.
- Neuraminic Acids in the Cerebrospinal Fluid
of Schizophrenic and Oligophrenic Pa-

- tients (C.N.); Gabriele Chistoni, 246, Sept. '60.
- On the Measurement of Adrenochrome in Blood (C.N.); I. Munkvad, 153, Aug. '60.
- Steps Toward the Isolation of a Serum Factor in Schizophrenia; Charles Frohman, 401, Nov. '60.
- Studies of Behavior and the Metabolism of Indole Derivatives in Schizophrenia; Nyla J. Cole, 393, Nov. '60.
- Urinary Excretion of Tryptophan Metabolites by Schizophrenic Individuals; P. Christine Brown, 63, July '60.
- Urinary Excretions (Corr.); 374, Oct. '60.
- Biography: William Malamud; Bernard J. Alpers, 11, July '60.
- Body Odor in Chronic Patients: Effects of a Drug on the (C.N.); Carl Gouldman, 354, Oct. '60.
